can be made either to lectures or to hospital practice. Medical practice.—Six months, 6*l.* 6*s.*; period required by Apothecaries' Hall, 12*l.* 12*s.*; unlimited, 21*l.* Surgical practice and dressing.—Six months, including three months' dressership, 8*l.* 8*s.*; twelve months, including six months' dressership, 12*l.* 12*s.*; eighteen months, including twelve months' dressership, 18*l.* 18*s.*; three years, including twelve months' dressership, 26*l.* 5*s.*; three years, including two years' dressership, 31*l.* 10*s.* Twelve months' dressership, after term of three years, 8*l.* 8*s.* The Hospital contains about 600 beds, thus allotted: Accidents and surgical cases, 324; medical cases, 179; diseases of women 13; children under seven years of age, 36; ophthalmic cases, 12; outdoor wards, 36. The completion of the new wing, of which the foundation was laid in June last, will raise the number of beds to 800. The Anatomical and Pathological Museum, the Materia Medica Museum, and the library are open daily.

ST. MARY'S HOSPITAL.—*Consulting Medical Officers.*—Sir James Alderson, M.D., F.R.S.; Dr. Chambers; Dr. Sibson, F.R.S.; Mr. Coulson; Mr. Lane; Mr. White Cooper. *Physicians.*—Dr. Handfield Jones, F.R.S., Monday, Thursday, 1.15; Dr. Sieveking, Tuesday, Friday, 1.15; Dr. Broadbent, Wednesday, Saturday, 1.15. *Assistant-Physicians.*—Dr. Cheadle, Tuesday, Friday, 1; Dr. Lawson, Wednesday, Saturday, 1; Dr. Shepherd, Monday, Thursday, 1. *Physicians for Diseases of the Skin.*—Dr. Handfield Jones, F.R.S., Thursday, Saturday, 1.15; Dr. Cheadle, Tuesday, Thursday, 1.30. *Surgeons.*—Mr. Spencer Smith, Monday, Thursday, 1.15; Mr. Haynes Walton, Thursday, Saturday, 1.15; Mr. James R. Lane, Tuesday, Friday, 1.15. *Assistant-Surgeons.*—Mr. Gascoven, Monday, Thursday, 1; Mr. Norton, Wednesday, Saturday, 1; Mr. Edmund Owen, Tuesday, Friday, 1.—*Physician-Accoucheur.*—Dr. A. Meadows, Tuesday, Friday, 9.30. *Assistant Physician-Accoucheur.*—Dr. Wiltshire, Tuesday, Friday, 1.30. *Surgeon of Ophthalmic Department.*—Mr. Haynes Walton, Monday, Thursday, 1.30. *Surgeon for Diseases of the Throat.* Mr. Norton, Wednesday, Saturday, 12.30. *Aural Surgeon.*—Mr. G. Field, Tuesday, Friday, 2. *Surgeon Dentist.*—Mr. Howard Hayward, Wednesday, Saturday, 9.30. *Lectures: Winter Session.*—Principles and Practice of Medicine (Dr. Chambers and Dr. Broadbent), Mondays, Wednesdays, and Thursdays, 4 P.M. Fee: One Course, 4*l.* 4*s.*; Unlimited, 6*l.* 6*s.* Principles and Practice of Surgery (Mr. James R. Lane and Mr. Gascoven), Tuesdays and Fridays, 4; Wednesdays, 3. Fee: One Course, 4*l.* 4*s.*; Unlimited 6*l.* 6*s.* Pathology.—Dr. Cheadle; Tuesday and Friday, 12. Fee: One Course, 3*l.* 3*s.* General Physiology.—Dr. Lawson; Wednesday and Saturday, 12. Fee: One Course, 3*l.* 3*s.*; Unlimited, 4*l.* 4*s.* Histology and Experimental Physiology.—Dr. Shepherd. There are two Courses; one for First Year's Students, at 10 o'clock, on Tuesday and Friday before, and on Tuesdays only after Christmas; the other, voluntary, for Second Year's Students, at the same hour on Wednesdays before, and on Wednesdays and Fridays after Christmas. Fee: For One Course, 3*l.* 3*s.*; Unlimited, 4*l.* 4*s.* Descriptive and Surgical Anatomy.—Mr. Norton; Monday, Tuesday, Thursday, and Friday, 2.45. Fee: One Course, 6*l.* 6*s.*; Unlimited, 8*l.* 8*s.* Practical Anatomy.—Mr. Edmund Owen, Demonstrator; Mr. G. M.

J. Giles, Assistant Demonstrator. The Dissecting Room is open every day, from 9 A.M. till 5 P.M., except on Saturday, when it is closed at 1 P.M. Students who have not entered to either the Anatomical or the Physiological Class of these classes can dissect on payment of a fee of 3*l.* 3*s.* for each Session. Each General Student pays a fee of 1*l.* 15*s.* at the commencement of the First and Second Winter Sessions for subjects. Chemistry and Physics. Dr. C. R. A. Wright, Mondays, Tuesdays, Thursdays, and Fridays, 9 A.M. Fee: One Course, 5*l.* 5*s.*; Unlimited, 7*l.* 7*s.* Dental Surgery.—Mr. Howard Hayward, Wednesdays and Saturdays, 9.30 A.M. Fee: 2*l.* 2*s.* *Summer Session.*—Materia Medica and Therapeutics.—Dr. Farquharson, Tuesday, Wednesday, Friday, and Saturday, 12 noon. Fee: One Course, 4*l.* 4*s.*; Unlimited, 6*l.* 6*s.* Midwifery and Diseases of Women and Children.—Dr. Alfred Meadows, Tuesday, Wednesday, Thursday, and Friday, 9 A.M. Fee: One Course, 4*l.* 4*s.*; Unlimited, 6*l.* 6*s.* Forensic Medicine and Public Hygiene.—Dr. Randall, Mondays, Wednesdays, and Thursdays, 10 A.M. Fee: One Course, 3*l.* 3*s.*; Unlimited, 4*l.* 4*s.* Botany.—Dr. Trimen, Mondays, Wednesdays, and Fridays, 10.30 A.M. Fee: One Session, 3*l.* 3*s.*; Unlimited, 4*l.* 4*s.* Practical Chemistry.—Dr. C. R. A. Wright, Inorganic Course, Tuesdays and Fridays, 10 A.M. Comparative Anatomy and Zoology.—Mr. St. George Mivart, F.R.S., Tuesdays and Thursdays, 11 A.M. Fee: One Session, 2*l.* 2*s.*; Unlimited, 3*l.* 3*s.* Ophthalmic Surgery.—Mr. Haynes Walton, Monday, 2.45. Fee for Course, 2*l.* 2*s.* Aural Surgery.—Mr. Field, Friday, 3. Fee for Course, 2*l.* 2*s.* Diseases of the Skin.—Dr. Cheadle, Thursday, 2. Clinical Lectures will be delivered as follows: Dr. Handfield Jones, every Thursday; Mr. Spencer Smith, every Monday; Dr. Sievekling, every alternate Friday; Mr. Broadbent, every alternate Saturday; Mr. Haynes Walton, every alternate Saturday; Mr. James R. Lane, every alternate Tuesday; Dr. Meadows, every alternate Tuesday. Mr. S. J. Knott, the Medical Tutor, will attend the Hospital daily in the Medical and Surgical Wards alternately, from 10 to 12 A.M., to direct and assist the Clinical Clerks, and afford the Students instruction in the Physical Examinations of such cases as the Physicians and Surgeons may allot for the purpose. He will teach the use of the Stethoscope and other instrumental aids to diagnosis, together with the systematic description and report of cases. The Hospital contains 170 beds, 68 of which are devoted to Medical and 102 to Surgical cases. A ward is appropriated to the Diseases of Women, and beds are provided for Ophthalmic cases. There is a Reading Room and Library in the Hospital, which is open daily for the use of the Students. It is partly supported by a grant from the school funds, and a fee of 1*l.* 1*s.* is paid on entrance by each student. The Museum is open daily to Students. It contains about 3,000 specimens illustrating healthy and morbid Human Anatomy, nearly 700 of which were presented by Mr. Lane; a number of preparations of the Genito-urinary Organs, with a collection of Calculi, by Mr. Coulson; a valuable Midwifery Series by Mr. North; and a Series of Wax preparations, illustrative of the Diseases of the Eye, by Mr. Ernest Hart. The specimens are arranged in Sections, and described in a Catalogue, so as to be available for reference. There is a very good Materia Medica Department, arranged in accordance with the British Pharmacopœia; and also a collection of specimens, illustrative of Comparative Anatomy, to-

gether with apparatus for illustrating the subject of Natural Philosophy.

Fees: Medical Practice, Three Months, 5*l.* 5*s.*; Six Months, 7*l.* 7*s.*; Twelve Months, 12*l.* 12*s.*; Eighteen Months, 15*l.* 15*s.*; Unlimited, 21*l.* Surgical Practice, Three Months, 6*l.* 6*s.*; Six Months, 9*l.* 9*s.*; Twelve Months (or the time required by the College of Surgeons), 21*l.*; Unlimited, 31*l.*; Entrance Fee to all the Lectures required for the Examinations at the Royal Colleges of Physicians and Surgeons, and the Society of Apothecaries, 52*l.* 10*s.*; Entrance Fee to the Hospital Practice required by the Royal Colleges of Physicians and Surgeons, and the Society of Apothecaries, 36*l.* 15*s.*; Entrance Fee to the Hospital Practice and Lectures required by the Royal College of Physicians and Surgeons and the Society of Apothecaries, 89*l.* 5*s.* in instalments, or 84*l.* in one sum. Entrance fee for unlimited attendance on the hospital practice, and all lectures delivered in the school, including one course of Practical Chemistry, 105*l.*, in instalments or 99*l.* 15*s.* in one sum; Entrance Fee to the Hospital Practice and Lectures required for the Examination in Dental Surgery by the Royal College of Surgeons, 52*l.* 10*s.* Students who have kept the two years' Course of Medical Study at the University of Cambridge are admitted as Perpetual Pupils on payment of a Composition Fee of 57*l.* 10*s.*, and Students who have kept a portion of the course there or elsewhere at a proportionate reduction. The entrance fees may be paid by instalments of 40*l.* at the commencement of the first year, 35*l.* at the commencement of the second year, and the remainder at the commencement of the third year, or in different sums by special arrangement with the Dean of the School. Students can make special entries to any of the Courses of Lectures, or to periods of hospital practice.

MIDDLESEX HOSPITAL.—*Consulting Physicians.* Dr. F. Hawkins, Dr. A. P. Stewart, Dr. Goodfellow. *Consulting Surgeon.*—Mr. Shaw. *Physicians.*—Dr. H. Thompson and Dr. Greenhow, Tuesday, Thursday, Saturday, 1; Dr. R. Swain, Monday, Wednesday, Friday, 1.30. *Obstetric Physician.*—Dr. J. Hall Davis, Tuesday, Friday, 1.30. *Assistant-Physicians.* Dr. Cayley, Monday, Wednesday, 8.30; Dr. Robert King, Thursday, 8.30, Saturday, 4; Dr. G. H. Evans, Tuesday, 4, Friday, 8.30. *Assistant Obstetric Physician.*—Dr. Arthur Edis, Wednesday, Saturday, 1.30. *Surgeons.*—Mr. De Morgan, F.R.S., Monday, Friday, 1; Mr. Nunn, Tuesday, Friday, 1; Mr. Hulke, F.R.S., Monday, Thursday; eye, Tuesday, Friday, 8.30; Mr. Lawson, Thursday, Saturday, 1. *Assistant-Surgeons.*—Mr. Morris, Monday, Friday, 1; cancer, Thursday, 1.30; Mr. Andrew Clark, Thursday, Saturday, 1. *Consulting Dental Surgeon.* Mr. Tomes, F.R.S. *Dental Surgeon.*—Mr. Turner, daily, 9. *Registrars.*—Mr. Sidney Coupland, M.B., Mr. Andrew Clark. *Resident Medical Officer.*—Mr. Lucas. *Chloroformist.*—Mr. G. Everitt Norton, operations, Wednesday, 1.

Lectures.—Winter Session.—Principles and Practice of Medicine.—Dr. Greenhow, F.R.S. Monday, Wednesday, and Friday, 9. Fee, one session, 6*l.* 6*s.*; unlimited, 8*l.* 8*s.* Principles and Practice of Surgery.—Mr. De Morgan, F.R.S. Monday, Wednesday, and Thursday, 3. Fee, one session, 6*l.* 6*s.*; unlimited, 8*l.* 8*s.* Practical Surgery.—Mr. Hulke, F.R.S., Mr. Lawson, and Mr. Morris. Monday and Thursday, 3. Fee, one course, 6*l.* 6*s.* Physiology and General Anatomy.—Mr. Lowne. Tuesday,

Thursday, and Saturday, 9. Fee, one course, 6*l.* 6*s.*; unlimited, 8*l.* 8*s.* Descriptive and Surgical Anatomy. Mr. Morris. Monday, Tuesday, Thursday, and Friday, 4. Fee, one course, 8*l.* 8*s.*; unlimited, 12*l.* 12*s.* Chemistry.—Mr. Heisch. Monday, Thursday, and Friday, 3; Saturday, 11. Fee, one course, 6*l.* 6*s.*; perpetual, 8*l.* 8*s.* Pathological Anatomy.—Dr. Cayley. Monday and Thursday, 4. Fee, one course, 4*l.* 4*s.*; unlimited, 5*l.* 5*s.* Parasitic Diseases. Dr. Cobbold, F.R.S. Clinical Lectures on Medicine.—The Physicians. Friday, 3. Clinical Lectures on Surgery.—The Surgeons. Friday, 3. Clinical Lectures on Diseases of Women and Children.—Dr. J. Hall Davis. Tuesday, 10. Clinical Lectures on Diseases of the Eye.—Mr. Hulke, F.R.S., Tuesday, 8.30. Dissecting-Room.—Mr. Hensman and Mr. Karop, Demonstrators. 9 to 4, daily. Fee for dissecting, one session, 6*l.* 6*s.*; unlimited, 8*l.* 8*s.*; course of lectures on anatomy, with dissection, one session, 10*l.* 10*s.*; unlimited, 14*l.* 14*s.* *Summer Session.*—Midwifery and Diseases of Women and Children.—Dr. J. Hall Davis. Tuesday, Thursday, and Saturday, 9. One session, 4*l.* 4*s.*; unlimited, 5*l.* 5*s.* Materia Medica and Therapeutics.—Dr. Thorowgood. Monday, Wednesday, and Friday, 4. One session, 4*l.* 4*s.*; unlimited, 5*l.* 5*s.* Medical Jurisprudence.—Dr. R. King. Monday, Wednesday, and Friday, 9. One session, 4*l.* 4*s.*; unlimited, 5*l.* 5*s.* Botany.—Mr. Hensman. Monday, Wednesday, and Friday, 10. One session, 4*l.* 4*s.*; unlimited, 5*l.* 5*s.* Practical Chemistry.—Mr. Heisch. Monday and Thursday, 3; Friday, 11.30. Fee per course, 3*l.* 3*s.* Practical Physiology and Histology.—Mr. Lowne. Monday, Wednesday, and Thursday, 9. Fee for session, 4*l.* 4*s.* Public Health.—Dr. G. H. Evans. Comparative Anatomy and Zoology.—Mr. Hensman. Tuesday and Thursday, 4. Fee per course, 3*l.* 3*s.* Psychological Medicine.—Dr. Henry Rayner. Fee for course, 3*l.* 3*s.* Clinical Lectures on Medicine and Surgery.—The Physicians. As in winter. Clinical Instruction on Diseases of the Eye.—Mr. Hulke, F.R.S. Tuesday and Friday, 11.30. Practical Demonstrations on Diseases of the Skin.—Dr. R. Liveing. Demonstrations on Diseases of the Larynx and Ear.—Mr. A. Clark. The Hospital contains upwards of 300 beds, of which 185 are devoted to surgical, and 120 to medical cases. There are 33 beds for cases of cancer; also wards for cases of uterine disease and of syphilis, and beds for cases of diseases of the eye. The Museum is open to students daily from 9 to 5. It contains above 5,000 specimens. The Library and Reading-Room are open to all general students. Occasional students may use the Library on payment of 1*l.* 1*s.* The College tutors, Mr. A. Clark and Mr. Sidney Coupland, assist all general students, especially those who are preparing for examination before any of the Licensing Boards. *Fee.*—General fee for attendance on the hospital practice and lectures, 90*l.*, if paid in one sum on entrance. The fee may be paid by instalments of 35*l.* on entrance, 35*l.* at the beginning of the second winter session, 20*l.* at the beginning of the third winter session, and 10*l.* for every additional year. Members of the University of Oxford, Cambridge, or Durham, who have completed one year of medical study at the University, are admitted to all lectures and hospital practice required by the Universities, or for the above-named qualifications, exclusive of practical chemistry, on payment of 55*l.* in one sum on entrance. This fee may be paid by instalments of 35*l.* on entrance, and 20*l.* at the

beginning of the second winter session; but students who pay by instalments will be required to pay 10*l.* for every additional year's attendance after the second year. For the instruction required by students who intend to become licentiates in dental surgery of the Royal College of Surgeons, 42*l.* in one payment, or 26*l.* 5*s.* on entrance, and 15*l.* 15*s.* at the beginning of the winter session.—Hospital Practice for Occasional Pupils: perpetual fee, 26*l.* 5*s.*; or instalments of 10*l.* 10*s.* at the beginning of the first year, 10*l.* 10*s.* at the beginning of the second year, 5*l.* 5*s.* at the beginning of the third year, and 5*l.* 5*s.* for every additional year after the third. For unlimited attendance on either medical or surgical practice separately, 15*l.* 15*s.*, in one sum. For one year's attendance on either medical or surgical practice separately, 8*l.* 8*s.* For six months' attendance on both medical and surgical practice, 7*l.* 7*s.*, or for either, 5*l.* 5*s.* Occasional pupils who do not enter at once for an unlimited period of attendance on hospital practice must pay a registration fee of 1*l.* 6*s.* Instruction in Dental Practice: fee for occasional students, 5*l.* 5*s.* Instruction in Pharmacy, without dispensing: three months, 4*l.* 4*s.* With dispensing: six months, 5*l.* 5*s.*, twelve months, 8*l.* 8*s.*

ST. THOMAS'S HOSPITAL.—*Consulting Physician.* Dr. J. Risdon Bennett. *Consulting Surgeon.*—Mr. F. Le Gros Clark. *Physicians.*—Dr. Peacock, Dr. Bristowe, Dr. Clapton, Dr. Murchison. *Obstetric Physician.*—Dr. Barnes. *Surgeons.*—Mr. Simon, Mr. Sydney Jones, Mr. Croft, Mr. Mac Cormac. *Ophthalmic Surgeon.*—Mr. Liebreich. *Assistant Physicians.*—Dr. Stone, Dr. Ord, Dr. John Harley, Dr. Payne. *Assistant Obstetric Physician.*—Dr. Gervis. *Assistant Surgeons.*—Mr. Francis Mason, Mr. Hy. Arnott, Mr. W. W. Wagstaffe. *Dental Surgeon.*—Mr. J. W. Elliott. *Assistant Dental Surgeon.*—Mr. W. G. Ranger. *Resident Assistant Physician.*—Dr. Turner. *Resident Assistant Surgeon.*—Mr. A. O. McKellar. *Demonstrator of Morbid Anatomy.*—Dr. Payne. *Analytical Chemist to the Hospital.*—Dr. Albert J. Bernays. *Curator of the Museum.*—Mr. C. Stewart. *Apothecary.*—Mr. R. W. Jones. *Registrars—Medical,* Mr. W. S. Greenfield; *Surgical,* Mr. S. Osborne. The physicians and surgeons commence their respective visits at fixed times, from 8.30 to 9.30. Operations on Wednesday and Saturday at 1.30, and Saturday at 9.30. Operations in the Eye Department on Thursday at 3. *Post mortem* examinations at 2.

Lectures.—Winter Session.—Demonstrations.—The Anatomical Lecturers, Mr. Rainey, Mr. R. W. Reid, and Assistants, daily, 9 to 3. Fee: single, 5*l.* 5*s.*; perpetual, 8*l.* 8*s.* Chemistry.—Dr. Albert J. Bernays, Tuesday, Thursday, Friday, 12. Fee: single, 5*l.* 5*s.*; perpetual, 8*l.* 8*s.* Physics and Natural Philosophy. Dr. Stone, Saturday. Fee: single, 3*l.* 3*s.*; perpetual, 4*l.* 4*s.* Theory and Practice of Medicine.—Dr. Peacock and Dr. Murchison, Monday, Thursday, or Friday, 2; Wednesday, 5. Fee: single, 5*l.* 5*s.*; perpetual, 8*l.* 8*s.* Morbid Anatomy and Practical Pathology.—Mr. Henry Arnott, Monday. Fee: single, 3*l.* 3*s.*; perpetual, 4*l.* 4*s.*; 10*s.* 6*d.* for expenses. Descriptive Anatomy.—Mr. Francis Mason and Mr. W. W. Wagstaffe, Monday, Tuesday, Thursday, Friday, 3; Wednesday, 12.30. Fee: single, 5*l.* 5*s.*; perpetual, 8*l.* 8*s.* Clinical Ophthalmic Surgery.—Mr. Liebreich, Monday, Thursday, 3. General Pa-

thology.—Dr. Bristowe, Thursday, 4. (See Morbid Anatomy.) Physiology and General Anatomy.—Dr. Ord and Dr. John Harley, Monday, Wednesday, Friday, 4. Fee: single, 5*l.* 5*s.*; perpetual, 8*l.* 8*s.* Clinical Midwifery.—Dr. Barnes, Tuesday, 4. Surgery.—Mr. Sydney Jones and Mr. Mac Cormac, Monday or Tuesday, Thursday, Friday, 5. Fee: single, 5*l.* 5*s.*; perpetual, 8*l.* 8*s.* Practical and Manipulative Surgery.—Mr. Croft, Monday or Tuesday, 5. Fee: single, 3*l.* 3*s.* *Summer Session.*—Botany.—Mr. A. W. Bennett, Tuesday, Thursday, Saturday, 8. Fee: single, 3*l.* 3*s.*; perpetual, 4*l.* 4*s.* Materia Medica.—Dr. Payne, Monday, Wednesday, Friday, 8. Fee: single, 3*l.* 3*s.*; perpetual, 4*l.* 4*s.* Practical and Manipulative Chemistry.—Dr. Albert J. Bernays, Tuesday, Thursday, Saturday, 11. Fee: single, 3*l.* 3*s.*; with 1*l.* 1*s.* 6*d.* for articles, etc. Comparative Anatomy.—Mr. C. Stewart, Monday, Wednesday, 11.30. Fee: single, 3*l.* 3*s.*; perpetual, 4*l.* 5*s.* Forensic Medicine and Hygiene.—Dr. Stone and Dr. Gervis, Monday, 2; Tuesday and Saturday, 12; Friday, 1. Fee: single, 3*l.* 3*s.*; perpetual, 4*l.* 4*s.* Mental Diseases.—Dr. Wm. Rhys Williams, Friday, 12. Fee: single, 2*l.* 2*s.*; perpetual, 3*l.* 3*s.* Practical Physiology.—Dr. Ord and Dr. John Harley, Monday, Thursday, Friday, 1.30 to 3.30. Fee: single, 3*l.* 3*s.*; with 1*l.* 1*s.* 6*d.* for expenses. Midwifery.—Dr. Barnes, Monday, Tuesday, Thursday, Friday, 3. Fee: single, 4*l.* 4*s.*; perpetual, 6*l.* 6*s.* Ophthalmic Surgery.—Mr. Liebreich, Monday, 4. Fee: single, 2*l.* 2*s.*; perpetual, 3*l.* 3*s.* Practical and Manipulative Surgery.—Mr. Croft, Tuesday, Friday, 4. Single, 3*l.* 3*s.* Admission fee to practice, and all the lectures, 40*l.* for the first year, a similar sum for the second, 20*l.* for the third, and 10*l.* for each succeeding year; or 105*l.* at one payment for unlimited attendance. Special entries may be made to any course of lectures, or to the hospital practice; and a modified scale of fees is arranged for students entering into their second, third, or any subsequent year. Fee for general subjects required for students of dental surgery for two years, 45*l.*, or instalments of 40*l.* for the first year, and 10*l.* for the second year. The hospital contains 569 beds, distributed as follows: medical, 180; surgical, 230; ophthalmic, 20; diseases of women, 20; venereal (women), 30; infectious diseases, 59; children under six years of age, 30. The museums of anatomy and pathology, and of materia medica and chemistry, are open to the students. Students have access to the library on payment of a fee of 1*l.* 1*s.* for the whole period of their studies. Laboratories, under the direction of the physiological and chemical lecturers, are provided. Instruction in practical pharmacy may also be obtained in the dispensary of the hospital, on payment of a fee of 5*l.* 5*s.* Private classes for students preparing for the preliminary scientific examination of the University of London, or for other examinations, are conducted by members of the staff, and embrace instruction in chemistry, natural philosophy, botany, and comparative anatomy.

UNIVERSITY COLLEGE HOSPITAL.—*Physicians.* Sir W. Jenner, Bart., K.C.B., M.D., F.R.S., Dr. R. Reynolds, F.R.S., Dr. Wilson Fox, F.R.S., Dr. S. Ringer, Dr. H. C. Bastian, F.R.S.: daily 1 and 2 P.M. *Obstetric Physician.*—Dr. Graily Hewitt, twice weekly. *Physician to Skin Infirmary.*—Dr. Tilbury Fox, Tues. 1.30; Sat. 9 A.M. *Assistant Physicians.*—Dr. F. T. Roberts, and Dr. W. R. Gowers. *Assistant Obstetric Physician.*—Dr. John Williams.

Surgeons.—Mr. Erichsen, Mr. Marshall, F.R.S., Sir Henry Thompson, Mr. Berkeley Hill, and Mr. Christopher Heath: daily 1 and 2 P.M. *Assistant-Surgeon.*—Mr. Marcus Beck. *Ophthalmic Surgeons.* Mr. Wharton Jones, F.R.S., and Mr. J. F. Streatfeild: Mon., Wed., Fri., 2 P.M. *Dental Surgeon.* Mr. Ibbetson: Wed., 10 A.M. *Holme Professor of Clinical Medicine.*—Dr. Wilson Fox, F.R.S. *Holme Professor of Clinical Surgery.*—Mr. Erichsen. *Assistant Teacher of Clinical Medicine.*—Dr. F. T. Roberts. *Surgical Registrar.*—Mr. Godlee. *Assistant Medical Officer in the Skin Department.*—Mr. Tweedy. *Resident Medical Officer.*—Mr. Meredith. Clinical Lectures are given by the Holme Professors and by the other Physicians and Surgeons; and pupils are specially trained in clinical observation and physical diagnosis. Fee: Hospital practice and clinical instruction, perpetual, 27*l.*; one year, 10*l.* Practical pharmacy, six months, 5*l.* 5*s.*; three months, 3*l.* 3*s.*

UNIVERSITY COLLEGE.—*Winter Session.*—*Principles and Practice of Medicine.*—Professor J. Russell Reynolds, M.D., F.R.S. Daily, except Mon., 9 A.M. Fee for the entire course, 6*l.* 6*s.*; perpetual, 9*l.* 9*s.* *Physiology.*—Jodrell Professor Burdon Sanderson, M.D., F.R.S.; Assistant Professor E. A. Schäfer; assistant, F. J. M. Page, B.Sc. Lond. Lectures on physiology on Mon., Wed., and Fri., 10, by the Jodrell Professor; on general anatomy on Tues. and Thurs. 10, by Mr. Schäfer. Fees for the entire course, 7*l.* 7*s.*; perpetual, 9*l.* 9*s.* A course of Practical Physiology and Histology, consisting of practical lessons in histology and the use of the microscope, and in physiological demonstrations, is given through the session; fee, 7*l.* 7*s.*; perpetual, 9*l.* 9*s.* Special courses of instruction in the use of the microscope and in the methods of histological work are given in the physiological laboratory. *Chemistry.*—Professor Williamson, Ph.D., F.R.S.; assistant professor, Charles Graham, D.Sc. Lectures daily, except Sat., 11. Exercises on Tues., Wed., Thurs., and Fri., 9 A.M. For the whole course of lectures, 7*l.* 7*s.*; perpetual, 9*l.* 9*s.*; for the organic course alone, 2*l.* 2*s.* Fee for the exercise class: for the course, 2*l.* 2*s.* *Anatomy.*—Professor G. Viner Ellis. Lectures daily, 12. Fee for lectures and practical anatomy: the entire course, 9*l.* 9*s.*; perpetual, to lectures, with three years' practical anatomy, 11*l.* 1*s.*; for practical anatomy, after the third year, every winter session, 1*l.* 1*s.*; for practical anatomy without attendance on lectures, for the three summer months, 3*l.* 3*s.* *Comparative Anatomy and Zoology.* Professorship vacant. Mon., Wed., and Fri., 3. Fee for comparative anatomy, 4*l.* 4*s.*; for zoology, 4*l.* 4*s.*; perpetual to both courses, 9*l.* 9*s.* *Principles and Practice of Surgery.*—Professor Marshall, F.R.S. Tues., Wed., and Fri., from 4 to 5 P.M. Fee for the course, 5*l.* 5*s.*; perpetual, 6*l.* 6*s.* *Practical Surgery.* This course consists of three distinct divisions, conducted by Mr. Berkeley Hill, Mr. C. Heath, and Mr. M. Beck. Fee for the entire course, 4*l.* 4*s.*, etc. *Dental Surgery.*—Lecturer, Mr. Ibbetson. Mon. and Thurs., 4. Fee, 2*l.* 2*s.* *Summer Session.*—*Botany.*—Professor Oliver, F.R.S. Daily, except Sat., 8. Fee for the session, 3*l.* 3*s.*; perpetual, 4*l.* 4*s.* *Midwifery and Diseases of Women.*—Professor Graily Hewitt, M.D. Tues., Wed., Fri., and Sat., 9 A.M. Fee for the session, 4*l.* 4*s.*; perpetual, 6*l.* 6*s.* *Practical Physiology.*—Professor Burdon Sanderson, M.D., F.R.S. *Pathological Anatomy.*—Professor H.

Charlton Bastian, M.D., F.R.S., Mon. and Thurs., 9 A.M.; Fri., 4 P.M. Fee for the session, 4*l.* 4*s.*; perpetual, 6*l.* 6*s.* *Medical Jurisprudence*.—Professor Maudsley, M.D., Tues., Wed., Thurs., and Fri., 10 A.M. Fee for the session, 3*l.* 3*s.*; perpetual, 4*l.* 4*s.* *Materia Medica and Therapeutics*.—Professor Ringer, M.D. Mon., 9; Tues., Wed., Thurs., and Fri., 10. Fee for the session, 4*l.* 4*s.*; perpetual, 6*l.* 6*s.* *Practical Chemistry*.—Professor Williamson, Ph.D., F.R.S. Elementary, Senior, and Summer Matriculation Courses. *Mental Diseases*.—Lecturer, W. H. O. Sankey, M.D. Mon., Tues., and Wed., 4 P.M. Clinical lecture at Camberwell House Asylum, Tues., 2 P.M. Fee 2*l.* 2*s.* *Operative Surgery*. Mr. C. Heath and Mr. M. Beck. Daily, at 8.30 A.M., or 3 P.M. Fee, including expenses, 4*l.* 4*s.* *Hygiene and Public Health*.—Professor Corfield, M.D. Tues. and Thurs., 4. Fee 1*l.* 1*s.* *Ophthalmic Medicine and Surgery*.—Professor Wharton Jones, F.R.S. Eight lectures, on Tues., 3 P.M. Fee, 1*l.* 1*s.*

WESTMINSTER HOSPITAL. — *Consulting Physicians and Surgeons*.—Dr. Kingston; Dr. Radcliffe; Mr. Lynn; Mr. Brooke; Mr. Barnard Holt. *Physicians*.—Dr. Basham; Dr. Fincham. *Surgeons*.—Mr. Holthouse; Mr. Cowell; Mr. Richard Davy. *Assistant-Physicians*.—Dr. Gibb; Dr. Sturges; Dr. Allchin. *Assistant-Surgeons*.—Mr. T. Cooke; Mr. T. Bond; Mr. Keene. *Obstetric Physician*.—Dr. Potter. *Assistant Obstetric Physician*.—Dr. Grigg. *Surgeon in charge of Ophthalmic Department*.—Mr. Cowell. *Surgeon in charge of Skin Department*.—Mr. Bond. *Surgeon in charge of Aural Department*.—Mr. Keene. *Dental Surgeon*.—Mr. Walker. *Medical Registrar*.—Dr. W. H. Allchin. *Surgical Registrar*.—Mr. W. R. Cheyne. *Winter Session*. — *Descriptive and Surgical Anatomy*.—Mr. R. Davy, Tues., Wed., Thurs., and Fri., at 12 A.M. Fees (including Dissections): One Course, 7*l.* 7*s.*; Two Courses, 10*l.* 10*s.* *Practical Anatomy*. Mr. Davy. *Demonstrators*.—Mr. Thomas Cooke and Mr. Verdon; *Assistant-Demonstrator*—Mr. Quicke. Fees: for Dissections only, Three Months, 2*l.* 2*s.*; Six Months, 3*l.* 3*s.*; for each subsequent session, 2*l.* 2*s.* *Chemistry*.—Dr. Dupré, Wed., Thurs., and Fri., 3. Fees: One Course, 5*l.* 5*s.*; Two Courses, 7*l.* 7*s.* *Physiology*.—Dr. Maclure, Mon., Wed., and Friday, 4 P.M. Fees: One Course, 5*l.* 5*s.*; Two Courses, 7*l.* 7*s.* *Practical Physiology and Histology*. Dr. W. H. Allchin, Tues. and Fri., 1 to 3 P.M. Fee: each Course, 4*l.* 4*s.* *Medicine*.—Mon., Wed., and Thurs., 3. Fees: One Course, 5*l.* 5*s.*; Two Courses, 7*l.* 7*s.* *Surgery*.—Mr. Cowell, Tues. and Thurs., 4, Fri., 3. Fees: One Course, 5*l.* 5*s.*; Two Courses, or one of this and the following Course, 7*l.* 7*s.* *Practical Surgery*.—Mr. Cowell, Tues. and Thurs., 4, Fri., 3. Fees: One Course, 5*l.* 5*s.*; Two Courses, or one of this and the above Course, 7*l.* 7*s.* *Diseases of the Skin*.—Mr. T. Bond, Thurs., 3, in February and March. Fee: each Course, 1*l.* 1*s.* Free to students of the Hospital. *Dental Surgery*.—Mr. J. Walker, Wed., 9.30 A.M. (in Oct., Nov., and Dec.). Fees: One Course, 2*l.* 2*s.*; Two Courses, 3*l.* 3*s.* Free to students of the Hospital, unless a certificate is required.—*Summer Session*. — *Materia Medica and Therapeutics*.—Dr. Sturges, Mon., Wed., and Thurs., 3 P.M. Fees: One Course, 3*l.* 3*s.*; Two Courses, 4*l.* 4*s.* *Botany*.—Mr. Holmes, Mon., Wed., and Fri., 9 A.M. Fees: One Course, 3*l.* 3*s.*; Two Courses, 4*l.* 4*s.* *Practical Chemistry*.—Dr. Dupré, Mon., Wed., and Fri., 10 to

12 A.M. Fee (inclusive of materials): each Course, 3*l.* 3*s.* *Midwifery and Diseases of Women and Children*.—Dr. Potter, Tues., Wed., and Fri., 4. Fees: One Course, 4*l.* 4*s.*; Two Courses, 5*l.* 5*s.* *Pathology and Morbid Anatomy*.—Dr. W. H. Allchin, Mon., 4, Tues., 9 A.M., and Thurs., 4 P.M. Fees: One Course, 3*l.* 3*s.*; Two Courses, 4*l.* 4*s.* *Forensic Medicine and Hygiene*.—Mr. Bond, and Dr. Dupré, Mon., Wed., and Fri., 3. Fees: One Course, 3*l.* 3*s.*; Two Courses, 4*l.* 4*s.* *Psychological Medicine*.—Dr. Sutherland. Fee: each Course, 1*l.* 1*s.* Pupils of the hospital free. *Ophthalmic Surgery*.—Mr. Cowell, Mon., 2.45. Fee: each Course, 1*l.* 1*s.* Free to students of the hospital, unless a certificate is required. *Minor Surgery and Bandaging*.—Mr. Cheyne, Wed. and Fri., 12. Fee: each Course, 1*l.* 1*s.* Free to students of the hospital, unless a certificate is required. *Operative Surgery*.—By the Lecturer on Anatomy. Fee: for One Course, including expenses, 4*l.* 4*s.* *Diseases of the Ear*.—Mr. Keene, Thurs., 9 A.M. Fee: each Course, 1*l.* 1*s.* Free to students of the hospital. *Comparative Anatomy*.—Dr. Carter Blake, Wed. and Sat., 11. Fees: One Course, 2*l.* 2*s.*; Two Courses, 3*l.* 3*s.* Free to students of the hospital, unless a certificate is required. *Natural Philosophy*.—Mr. Brooke, F.R.S., Tues., 3. Fee: each Course, 1*l.* 1*s.* Free to students of the hospital. Fees for hospital practice and lectures required by the Colleges of Physicians and Surgeons in London, and the Society of Apothecaries; one payment of 8*ol.*, or two of 4*ol.*, each at commencement of first two academical years. The payments may also be distributed in other ways, which may be learned on application at the hospital. The hospital contains 191 beds. Pupils who enter for the whole period of medical education are permitted to attend, without further fee, the practice of the Royal Westminster Ophthalmic Hospital, and that of the National Hospital for Paralysis.

TEXT-BOOKS.

In making the remarks on text-books which appear below, our object is simply to direct the student's attention to those works which he is likely to find most useful. To say always which book on any subject is the best that every student can use, is difficult, if not impossible. In some instances the characters of the books are very nearly balanced; again, some text-books may be better suited than others to the teaching of the school to which the pupil belongs; and further, one student may be able to learn better from a large book, and another from a small one. All the books, however, that we mention, may be safely trusted. In addition to text-books to be used as guides from the commencement of and throughout the study of any one department, we mention also several works from which instruction in various points may be obtained, although we do not recommend the student to peruse them through-out.

ANATOMY.

The old and well tried text-books of Anatomy, renewed from time to time by competent editors, continue to find favour with students. The well-known Quain's *Elements of Anatomy*, edited by Drs. Sharpey, Allen Thomson, and Cleland (Longmans & Co., 2 vols., 3*l.* 6*ol.*) holds, as it has long done, the first place. An old acquaintance, of late some-

what forgotten, Wilson's *Anatomist's Vade Mecum*, has lately reappeared, edited by Dr. George Buchanan, of Glasgow (J. and A. Churchill, 14s.) The work was in great favour with students a quarter of a century ago, and in its new form will no doubt be found useful by students who prefer a work of moderate size. A book which, we believe, has much favour in Ireland, is Messrs. Ledwich's *Practical and Descriptive Anatomy* (Dublin: Fannin; London: Longmans & Co., 12s. 6d.) Among manuals for the dissecting room there is in the first place Mr. Viner Ellis's excellent *Demonstrations of Anatomy* (Smith, Elder & Co., 12s. 6d.) There is also an useful companion to this book in the form of a series of coloured life-size plates, by Mr. Ellis and Mr. Ford (Smith, Elder, & Co., 6l. 6s.); but from its price this is a work which most students will be content to examine—which they may do with advantage—in the dissecting rooms or libraries of their schools.* Other good books for the dissecting room are Mr. Holden's *Manual of Dissections* (J. and A. Churchill, 16s.); and Mr. C. Heath's *Practical Anatomy* (J. and A. Churchill, 12s. 6d.) Mr. Thomas Cooke's *Tablets of Anatomy and Physiology* (Longmans) present highly useful analyses of the anatomy of various parts in a condensed form. For students of Osteology Mr. Luther Holden has in preparation a fifth edition of his work on *Human Osteology*, with plates (J. and A. Churchill); and a second edition of Mr. A. T. Norton's *Osteology for Students* (Baillière, Tindal, and Cox, one vol., 7s. 6d.; two vols., 8s. 6d.) has lately been issued. Other works which the student would do well to possess, are Mr. St. John Mivart's *Elementary Lessons in Anatomy* (Macmillan & Co., 6s. 6d.) in which the author not only gives the well known elementary parts of human anatomy, but renders their study more interesting by pointing out the more significant relations in the structure of man to that of other animals. Having touched on the subject of Comparative Anatomy, we would here mention as books which every anatomical pupil should study at some period, Professor Flower's *Introduction to the Osteology of the Mammalia* (Macmillan & Co., 7s. 6d.); and Professor Huxley's *Manual of the Anatomy of Vertebrated Animals*, (J. and A. Churchill, 12s.) In Physiology, the principal English work is Dr. Carpenter's *Principles of Human Physiology*, edited by Mr. H. Power (J. & A. Churchill, 28s.) There is also in preparation (by the same publishers) a fifth edition of Dr. Carpenter's *Manual of Physiology*, a work which has been in good reputation. Dr. Kirkes's *Handbook of Physiology*, edited by Mr. Marrant Baker (John Murray, 12s. 6d.) is an excellent epitome. There is also announced as in preparation, a translation, by Dr. Arthur Gamgee, of the *Elements of Human Physiology*, by Dr. L. Hermann of Zurich (Smith, Elder & Co.) Dr. Dalton's *Treatise on Human Physiology* (Smith, Elder & Co., 28s.), is an useful book.

Regarding Histology, much information will be found in the various works on Anatomy and Physiology, a section of Quain's *Anatomy* being especially devoted to the subject. A work to be consulted with much advantage is the excellent collection of essays on *Human and Comparative Histology*, edited by Professor Stricker, and translated by the New Sydenham Society. As, however, it can scarcely be

obtained otherwise than by three years' subscription to the Society, its possession will not be in the power of many students.

MEDICINE.

Of text-books on Medicine, there is no deficiency. In the foremost rank among them stands that classical work, Sir Thomas Watson's *Lectures on the Principles and Practice of Medicine* (Longmans & Co., 2 vols., 36s.). The late Dr. Tanner's *Principles and Practice of Medicine* (Renshaw, 2 vols., 38s.) gives a good summary of modern views and treatment. Dr. Aitken's *Science and Practice of Medicine* (C. Griffin & Co., 2 vols., 38s.) is a book which students preparing for University examinations can scarcely dispense with; and there is also announced to appear shortly, a text-book by the same author under the name of *Outlines of the Science and Practice of Medicine*. Other books to be recommended for the use of the student are, *Guy's Hooper's Physician's Vade Mecum*, edited by Dr. John Harley (Renshaw, 12s. 6d.)—a book in which some will find rather an excess of condensation; Dr. F. T. Roberts's *Handbook of the Theory and Practice of Medicine* (H. K. Lewis, 16s.); Dr. Barlow's *Manual of the Practice of Medicine*. The advanced student will do well to read—and possess if he can—Dr. Russell Reynolds's *System of Medicine* (Macmillan & Co., 25s. each volume) of which the last (fourth) volume is still unpublished; and Trousseau's *Lectures on Clinical Medicine*, translated for the New Sydenham Society by Dr. Bazire and Sir J. R. Cormack, of which copies can be had without subscription to the Society (H. K. Lewis, 5 vols., 35s.)

As elementary aids in the study of medical diagnosis, there are several good works which the student should possess; viz., Dr. O. Sturges's *Introduction to the Study of Clinical Medicine* (Smith, Elder & Co., 4s. 6d.); Dr. Barclay's *Manual of Medical Diagnosis* (J. & A. Churchill, 10s. 6d.); and Dr. G. Fenwick's *Student's Guide to Medical Diagnosis* (J. & A. Churchill, 6s. 6d.). A more extensive work on the same subject, fitted for advanced students and capable of being consulted with advantage by practitioners, is Dr. Da Costa's *Medical Diagnosis* (Smith, Elder & Co., 24s.). Dr. Gee's *Auscultation and Percussion* (Smith, Elder & Co., 5s. 6d.) is an excellent guide to the physical examination of the chest.

SURGERY.

As a text-book of operative surgery, Sir William Fergusson's *System of Practical Surgery* (J. and A. Churchill, 21s.) is a book which should be in the hands of every student. In its description of minor surgery, of fractures and dislocations, and of surgical operations, it is excellent. In pathology, however, it is deficient, and requires to be supplemented in this respect by other works. Mr. Erichsen's *Science and Art of Surgery* (Longmans and Co., 2 vols., 32s.) is an excellent practical work, and at the same time gives a sufficient outline of pathology. It is a very complete work, and is much used. A smaller work containing much useful information both as to pathology and practice, given in an easy style, is Druitt's *Surgeon's Vade Mecum* (Renshaw, 12s. 6d.), a long well known and trustworthy guide. Dr. Pirrie's *Principles and Practice of Surgery* (J. and A. Churchill, 28s.) represents

* A number of these plates appear in a reduced form in a new edition of Mr. Ellis's *Demonstrations*, which is announced.

the teaching of the Aberdeen school, and is much used by its students. Among other works of value which the student and practitioner of surgery may consult with advantage, are the late Professor Syme's *Principles of Surgery*, a book containing much valuable practical advice, the result of the author's experience; Mr. Spence's *Lectures on Surgery* (A. & C. Black), valuable for its practical instruction, illustrated by records of cases; Mr. Bryant's *Practice of Surgery* (J. & A. Churchill, 21s.); Mr. Holmes's *System of Surgery* (Longmans & Co., 5 vols., 5l. 5s.); Cooper's *Dictionary of Practical Surgery*, edited by Mr. Lane (Longmans and Co., 2 vols., 50s.); Mr. Gant's *Science and Practice of Surgery* (J. & A. Churchill, 24s.); and Dr. Gross's *System of Surgery* (Smith, Elder & Co., 70s.).

There are several very good guides, fitted for the use of the student who is being instructed in practical and operative surgery. Mr. Christopher Heath's *Manual of Minor Surgery and Bandaging* (J. & A. Churchill, 5s. 6d.); Mr. Annandale's *Surgical Aphorisms and Minor Operative Surgery*; Dr. Joseph Bell's *Manual of the Operations of Surgery* (MacLachlan & Stewart, 6s.), and Mr. Maunder's *Operative Surgery* (J. & A. Churchill, 6s.), are all books to which the student may trust for useful information. Mr. Bellamy's *Student's Guide to Surgical Anatomy* (J. & A. Churchill, 6s. 6d.) is a comparatively recent work, which will no doubt be found acceptable.

MIDWIFERY.

The most complete modern British text-book on this subject is Dr. Leishman's *System of Midwifery* (Macmillan and Co., 1l. 10s.); which, though some points of much importance are passed over without allusion or in an insufficient manner, is an excellent and well written work. Another valuable book of large size is Dr. Bullock's American edition of Cazeaux's *Treatise on Midwifery* (Philadelphia, Blakiston). For students who prefer smaller books, Dr. Alfred Meadows's *Manual of Midwifery* (Renshaw) will be found valuable. A translation by Dr. C. H. Carter of Schröder's *Manual of Midwifery* (J. and A. Churchill, 12s. 6d.) has lately appeared. Dr. J. G. Swayne's *Obstetric Aphorisms* (J. and A. Churchill, 3s. 6d.) is a little work which, though it cannot take the place of a text-book, will serve as an useful 'remembrancer' to the student and practitioner. The advanced student, and the practitioner also, of midwifery, should possess Dr. Robert Barnes's *Lectures on Obstetric Operations* (J. and A. Churchill, 15s.).

PATHOLOGY.

The best manual for the English student commencing the study of pathology is Dr. T. H. Green's *Introduction to Pathology and Morbid Anatomy* (Renshaw, 9s. 6d.). It is concise and clearly written, and well calculated to give the student a sound idea of the general principles of the subject. Beyond this, there can scarcely be said to be a text-book of English growth which is at the level of the time; although Sir James Paget's *Lectures on Surgical Pathology*, edited by Professor Turner (Longmans & Co., 21s.), will still be read by the advanced student as a text-book of surgical pathology, and as a model of scientific work recorded in clear and elegant language. A work which we would strongly recommend is Professor Billroth's *Surgical Pathology*

and *Therapeutics*, translated by Dr. Hackley (H. K. Lewis, 18s.). It contains a very complete summary of modern views, and the explanations are ample and clearly given. Dr. Rindfleisch's *Manual of Pathological Histology*, translated for the New Sydenham Society by Dr. Buchanan Baxter, is an excellent work, which the advanced student would do well to consult whenever he has an opportunity. Its possession requires two years' subscription to the society.

MATERIA MEDICA AND THERAPEUTICS.

As a manual of materia medica, Dr. Garrod's *Essentials of Materia Medica and Therapeutics*, edited by his successor in the chair of Materia Medica at King's College, Dr. Buchanan Baxter (Longmans & Co., 12s. 6d.) is a very useful book, though the material is much condensed. It treats, however, but briefly of therapeutics, and requires to be supplemented by other books on this subject. For this purpose, Dr. Ringer's *Handbook of Therapeutics* (H. R. Lewis, 12s. 6d.) and Dr. Waring's *Manual of Practical Therapeutics*, are to be recommended. Among larger works, which the student may use with advantage as text-books, are Bentley and Redwood's edition of Dr. Pereira's *Elements of Materia Medica and Therapeutics* (Longmans & Co., 25s.) and Dr. Macnamara's edition of Neligan's *Medicines* (Farman & Co., and Longmans & Co. 18s.). In Dr. H. C. Wood's treatise on *Therapeutics* (Smith, Elder & Co., 12s. 6d.) special attention is paid to the important subject of the physiological action of drugs. A *Manual of Materia Medica and Therapeutics*, comprising pharmacy and the physiological and therapeutic action of medicines, by Dr. Lauder Brunton, is announced as forthcoming by Smith, Elder, & Co. When it appears, it will, without doubt, be a book which should be in the hands of every student.

REVIEWS.

Science Primers—Physiology. By MICHAEL FOSTER, M.A., M.D., F.R.S. London and Cambridge: Macmillan and Co. 1874.

The importance of physiology, not only as a department of medical knowledge, but as a branch of general information, both useful and interesting, has become much more generally acknowledged, and the science is much more widely taught than it was when the reviewer first became acquainted, as a school-boy sixteen or seventeen years ago, with the *Text Book of Physiology for Schools*, published by Messrs. W. and R. Chambers, of Edinburgh. Increased demand for instruction has not only increased the supply, but greatly raised the quality; and excellent in its way though the text-book of Messrs. Chambers was, it could not stand comparison with those recently issued by Messrs. Macmillan, written as they are by Huxley and Foster, masters of the English language as well as physiologists of the greatest eminence. The primer of Foster is much shorter and is also simpler than the lessons of Huxley. It is intended for younger children, and will serve admirably as an introduction to the larger work. Instead of beginning, as less able men would have done, with a statement of facts which a scholar might get up by rote, but which would not interest him and would consequently

be soon forgotten, Dr. Foster first tries to awaken the child's curiosity and entices instead of drives him to learn. The introduction commences as follows:—"Did you ever, on a winter's day, when the ground was hard as a stone, the ponds all frozen, and everything cold and still, stop for a moment as you were running in play along the road or skating over the ice to wonder at yourself and ask these two questions—"Why am I so warm when all things around me, the ground, the trees, the water, and the air are so cold? How is it that I am moving about, running, walking, jumping when nothing else that I can see is stirring at all except perhaps a stray bird seeking in vain for food?" These questions Dr. Foster then proceeds to answer fully, clearly, accurately, and yet in simple language, insisting upon and repeating the most important points so that the scholar shall get them deeply impressed on his mind without being confused by a mass of details. Notwithstanding the small size of the book, it contains an account of the parts of which the body is made up; what takes place when we move; the nature of blood; how the blood moves; how the blood is changed by air; breathing; how the blood is changed by food; digestion; how the blood gets rid of waste matters; the whole story shortly told; how we feel and will. From this list, it is evident that the primer contains an account of the most important physiological processes; and, although it is intended for children, it may be read with great profit by those of any age who are attempting for the first time to acquire a knowledge of physiology.

T. LAUDER BRUNTON, M.D.

MISCELLANY.

AMONGST those who will probably be candidates for the Professorship of Zoology and Comparative Anatomy, now vacant in University College, London, are Mr. E. Ray Lankester, Dr. J. Murie, and Mr. H. Seeley.

DR. ALLEYNE NICHOLSON has been appointed to the chair of Biology and Physiology about to be established in the Durham University College of Medicine and Physical Science, at Newcastle-on-Tyne.

UNDER the Principalship of Monsignor Capel, a Catholic College is shortly to be opened in Kensington, in which the natural sciences will be taught without restrictions. A museum, a laboratory, and lecture-rooms are in readiness; and in the Educational department more than one appointment has already been made. Mr. St. George Mivart is to lecture on zoology during the winter months, and on botany in the summer. Mr. Barff is to lecture on chemistry.

THE INSECT WORLD.—An exhibition, interesting alike to the entomologist, the horticulturist, and the agriculturist, is now open in the orangery in the gardens of the Tuileries. This exhibition contains specimens of all known insects, those which yield products useful to man, as silkworms, bees, etc., as well as those which are sometimes so destructive to the crops and orchards, as the various kinds of beetles and caterpillars. Every sort of insect, from the smallest to the largest, may be studied here, as with true French system they are all labelled with explanatory descriptions, whilst the products of the useful insects and specimens of the ravages committed by the destructive ones are also shown in impressive contrast. Models of beehives, all kinds of contrivances for destroying the pests of the insect world, with all descriptions of horticultural inventions and appliances, help to increase the utility and interest of this exhibition.

DEATH OF DR. ANSTIE.—With much regret we announce the death of Dr. F. E. Anstie, physician to and lecturer on medicine at the Westminster Hospital. He died on Saturday last after an illness of three days, brought on by exposure to sewer emanations while examining the sanitary defects of a school at Wandsworth early in the week. Dr. Anstie had made some valuable contributions to medical literature on alcohol, neuralgia, and other subjects. His death will be felt as a great loss to the profession.

FEMALE APOTHECARIES.—The *Philadelphia Medical Times*, in an article on the new movement for obtaining employment for women, comments on the fact that no women are brought up in America to the practice of pharmacy. It advocates this business as a very suitable avocation for women who are properly trained to be careful and accurate; and dilates on its freedom from the objections which are usually urged against women entering the medical profession. The opening up of this branch of employment to women in England is observed with pleasure by our contemporary, which goes on to enumerate in detail the facilities given by the New Apothecaries Act to women desirous of becoming chemists and druggists.

A CHEQUERED CAREER.—The *Journal de Constantinople* records the death of a member of the medical profession, who had not always followed the peaceful paths of the healing art, but had helped in his day to find some occupation for the skill of the surgeon. Abdullah Bey, or Karl Hammerschmidt, for such was his real name, was born in Vienna, the son of an Austrian government official. In his early days he obtained an European reputation as an entomologist and writer on rural economy, but was diverted from these scientific pursuits by the Vienna revolution of 1848, in which he took a prominent part. He afterwards assisted Kossuth, as far as lay in his power, in the Hungarian struggle with Austria, fighting with the Magyars under General Bem. On taking refuge at Constantinople he was appointed tutor in the medical school; but, the Austrian Government objecting to his residence there, he removed to Damascus, where he spent several years as a hospital surgeon. After the Crimean War he returned to the Turkish capital and became Professor of Mineralogy and Zoology. His collection of insects, which gained a gold medal at the Paris Exhibition, was accidentally burnt. His death is attributed to his undertaking, at the age of seventy-four, some geological researches in Asia Minor.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17s. 4d.; free by post, 19s. 6d.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & CO., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The First Volume, containing upwards of Two Thousand Articles abstracted and compiled by a staff of Fifty Hospital Surgeons and Physicians, is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for the year 1873 are also ready, price 1s. 6d. each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & CO.—Calcutta: THACKER, SPINK & CO.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & CO.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & CO., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, SEPTEMBER 23, 1874.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

GUILLEMIN ON TYPHUS FEVER.*

From the fact that the origin of some cases and some epidemics of typhus fever has been traced to contagion, it has been by many most illogically concluded that all cases and all epidemics of the disease in question must be due to the same cause. In the interesting monograph before us, Dr. Guillemin has presented to us very important facts bearing upon this question—facts which, we believe, establish the doctrine that typhus fever may arise spontaneously in certain well-known unsanitary conditions; and that, in fact, in several remarkable instances it has actually arisen so. Dr. Guillemin commences by contesting the opinion of Professor Chauffard, expressed in a communication to the Academy of Medicine on October 15, 1872. This last-mentioned writer, reviewing the circumstances of the civil and military population in Paris and Metz during the late war, maintained that all the generally admitted causes of typhus epidemics existed in these towns in full force, and that notwithstanding there was no typhus. From this M. Chauffard not only denies the possibility of a spontaneous origin of typhus in France, but generally the possibility of the spontaneous origin of typhus epidemics. It would be sufficient, in opposition to this (says Dr. Guillemin), to show 'either that the conditions which render the spontaneous explosion of typhus inevitable neither existed at Paris nor at Metz, or that cases of typhus were observed in one or other of these two towns. One is not permitted,' he continues, 'in order to solve the question of the origin of an epidemic disease, to limit one's self to a study of the circumstances in which it has not appeared; for, even supposing M. Chauffard's assertions perfectly established—that is to say, first, that typhus was not observed either at Paris or at Metz; and, second, that all the conditions generally recognised as leading to its production were found combined there—that by no means authorises us to infer the necessity of importation. We may with as much reason conclude that, if the action of the habitual causes of typhus have not produced its ordinary effects, this is because it has been trammelled by circumstances which have escaped observation, and which ought to be sought after.' Dr. Guillemin maintains that the absence of typhus from Paris and Metz, even if true, which it was not, would not justify M. Chauffard's conclusions. It would have been necessary, in order to do this, says the author, 'to pass in review the epidemics of typhus upon the origin of which we

have positive information, to study the conditions in which they were produced, and to show that importation has been the condition *sine quâ non* of their appearance. This has not been done; indeed, it could not be done, seeing that there is a large number of epidemics of typhus in regard to which importation is in no way admissible.'

Passing in review the work of Pringle, whom our author quotes, as supporting the spontaneous theory of the origin of typhus in individuals and communities placed in conditions of organic deterioration, subject to overcrowding and general unsanitary conditions, he proceeds to show how these causes gave rise to typhus in the French and English armies in the Crimea.

The French troops were forwarded to the Crimea in September, 1872, and the first typhus epidemic appeared in the following December, at a time when the severe cold condemned the soldiers to suffer from overcrowding and deficient ventilation. Félix Jacquot thus graphically describes the condition of the French. 'After a prolonged stay in the mud of the trenches, after sentry duty, general labour, road-making, marches in deeply cut up and sinking fields, after having been soaked by rain and snow, the soldiers shivering, and very often wanting in changes of raiment, crowd themselves under the tents and huts, light if they can a meagre fire, and close hermetically all the openings with a perseverance and pertinacity against which the most pressing counsels and the most severe measures fail. The extreme uncleanness of the men, the fetid expirations, tobacco smoke, the evaporation from the wet clothing, all unite to make these narrow holes pestilential. Within is typhus, without is frost-bite, pushed often to complete sphacelus of the feet. The danger appears everywhere, but the worst is within.'

Almost at the same time typhus appeared in the English and Russian armies in the Crimea, and in the Russian and Turkish armies in Asia. At the end of 1855, the conditions which we have mentioned persisting with even increased force, a second epidemic of typhus broke out in the month of December, and raged with greater violence than the first. The weather was extremely cold, the thermometer falling sometimes to 7.5° or 11° below zero Fahr. The overcrowding was excessive, ambulances originally constructed for 200 or 400 men often containing twice or three times that number. It may be said, says Dr. Guillemin, that these circumstances only favoured the transmission of the disease to a large number of persons, and that the second epidemic was due to sporadic cases occurring from the time of the decline of the first. 'This opinion,' continues our author, 'becomes very difficult to defend if we compare the sanitary state of our army with that of the English army at the same time. During the first year of the war the English, for a long period unaccustomed to war, did not know in time how to take proper measures to place their army in the best possible hygienic condition; it was as badly nourished, as badly lodged, as ours; it was decimated by typhus. But, contrary to what happened with us, the English knew how to profit by the rude lessons of experience; they understood that prevention was more easy than cure; after having recognised the cause of the evil, they did not hesitate to make the necessary sacrifices to suppress it; their soldiers were lodged in well-constructed, well-aired, and well-heated barracks; there was an abundance of good food, and measures were taken to avoid overcrowding. What happened?

* *Les Origines et la Propagation du Typhus.* Par le Dr. J.-F. Guillemin, médecin-major des hôpitaux militaires. G. Masson: Paris. 1874.

The English army almost completely escaped the second epidemic, which affected the French army to a greater extent than the first.

Is not this experiment on a large scale the most striking demonstration which could possibly be given of the spontaneous origin of typhus? The two armies are placed side by side on the same soil; the one, badly fed, placed in deplorable conditions, subjected to the influence of overcrowding pushed to its most extreme limits, and counting in its ranks a large number of men exhausted by intestinal affections, scorbutus, and anæmia, is a prey to typhus; the other, well fed, placed in good hygienic conditions, provided with ambulances and hospitals in which the greatest care is taken to prevent overcrowding, is spared by typhus.

In 1861 MM. Léonard and Marit reported upon a severe epidemic of typhus which appeared in two villages in Algeria. The epidemic occurred in the month of February, and was strictly confined to these two villages, which were noted for their entire disregard of sanitary requirements. The houses, or rather hovels, consisted of a ground floor almost level with the soil; there were no windows, the only openings being the doors; the lanes and courts served as so many dépôts for dirt and every kind of excrement. Each of these holes would contain from eight to nine persons, with certain domestic animals in addition. The bare humid soil, tainted with ordure, formed the family couch. 'Here, then,' says Dr. Guillemin, 'is an epidemic with which importation had nothing to do. The importation could have taken place in but two ways: either the typhus had gained these two villages by propagating itself gradually from one locality to another—and then its tract could have been followed, inasmuch as it would have affected other populations before reaching the heart of Kabylie. Now the epidemic was quite circumscribed and perfectly localised in the two villages of Seddouck and Immoula; it had not been noted previously in any of the neighbouring villages. Or the typhus had been imported by isolated individuals coming from some locality more or less distant where it existed at the same time; this supposition is as inadmissible as the first, for typhus at that time had not been observed in any other part of Algeria.'

Dr. Guillemin says that the epidemic of Kabylie proves that importation is not so easy as some imagine; inasmuch as, notwithstanding that no precautions were taken to prevent importation or exportation, the surrounding villages remained free from the disease.

In the typhus epidemic which appeared in Algeria in 1868, the same unsanitary conditions which prevailed in the Crimea existed in full force. The first cases in general came either from overcrowded prisons and asylums, or from ambulances and hospitals into which the native sick had been admitted. In the spring of 1863, however, typhus had appeared in the town of Constantine, and continued there in a sporadic form 'pendant les années suivantes.' It was, so to speak, acclimatised there, so that the first notion of some physicians was to attribute the epidemic of 1868 to contagion from that of 1863. This view might be maintained if one ignored the fact that at the time ('même moment') when the disease exploded at Constantine it showed itself equally in a great number of localities of the two other provinces of Algeria, 'where typhus had never been observed till then either in the epidemic or the sporadic state.' For, at the time when that the

epidemic broke out in Constantine, it showed itself at Orléansville, Oran, Tlemcen, Mascara, Bel-Abbés, etc., localities very remote from the first, and which had no direct communication with it. Under these circumstances, one is compelled to admit that no relation could be established between the endemic of Constantine in 1863 and the epidemic of 1868.

In the second part of his monograph, Dr. Guillemin treats at length of the formation of typhus centres, of which, he says, the chief causes are overcrowding, especially overcrowding of the sick and wounded, uncleanness, starvation, and the association of persons suffering from diarrhœa, dysentery, erysipelas, gangrene, etc.; and certain facts authorise him to state that this may occur in the open air. In this division of his work he mentions that in the penitentiary of Ain-el-Bey the first case of typhus showed itself in an infirmary assistant, whose duty it was to dress suppurating wounds, at a time when there was not a single case of typhus in the penitentiary.

Speaking of Metz, Dr. Guillemin maintains, contrary to the received opinion, that there were undoubted cases of typhus in that town, and that, if it had not capitulated, these cases would have reached the dimensions of an epidemic. But the condition of Metz was by no means very bad. As to food, 'without doubt it was deficient, but those who have not looked into the matter closely form a false idea of the extent of this deficiency; they forget that butcher's meat never failed, and that the daily allowance of it had been even largely increased, since "dans les derniers temps" it reached 750 grammes, *i.e.* nearly two pounds; it is true it was horseflesh, but this remained during the whole time of sufficient quantity.' Dr. Guillemin informs us that bread only became scarce about fifteen days before the capitulation. At best then it was of passable quality, and, although diminished in quantity, strictly sufficient. Only in the two or three last days distribution of bread had entirely ceased, and then only the soldiers begun to suffer from hunger, although they still had meat.

'Many among them were very feeble, it is true, but they were not cachectic; no one had observed among them scurvy, as in the Crimea, nor that feeble condition of body due to starvation; there was neither epidemic diarrhœa nor dysentery. To sum up, in the army camped round the town there were no encumbrances, no great fatigue, no antecedent disease, and, consequently, no organic deteriorations; there was, indeed, insufficiency of food, but only for a fortnight or three weeks at most.'

In the last chapter of the second part of Dr. Guillemin's paper, he refers to the spontaneous origin of typhus in France, and gives several instances, such as the epidemic in the convict prison of Toulon in 1830; that of Strasburg prison in 1854; that of the prison of Nancy in 1854-55, etc. In none of these cases could importation be traced, 'although,' says our author, 'one may always, it is true, to explain the appearance of an epidemic, allege importation even when it is not possible to prove it; it is easy to say that the importation has passed unperceived; this is a convenient proceeding, but not a serious argument; importation ought, in my opinion, to be rejected when it is neither proved nor probable.'

From these statements we think it may be fairly concluded, that typhus is a disease which may arise spontaneously under certain well-known conditions;

and whenever these conditions exist in sufficient force. The assertion that the origin of the disease is always due to contagion is a pure assumption, for unless it be eternal, which no one has as yet affirmed it to be, it must have commenced some time; and the conditions which gave rise to its first appearance may have given rise to some of its subsequent appearances. And there is not only no proof that these conditions are now non-existent, but much that they are existent, and that they appear and disappear at certain periods, and always under the same or similar conditions. Indeed, to such an extent is this true that epidemics of typhus may be predicted, as Dr. Murchison says, 'with tolerable certainty,' or, as Jacquot says, 'typhus may be produced at will.' 'If,' says Dr. Murchison, 'in the case of every epidemic of typhus the first patient has contracted the disease from a person formerly infected, although it is impossible to trace the source, the contagion must needs be most potent and indestructible, which is the very reverse of the truth. The poison of typhus requires neither heat nor disinfectants for its destruction, but at once becomes inert on free admixture with fresh air. The opponents of the independent origin of typhus, in order to account for certain epidemics, are under the necessity of contending that the contagion exists in every part of the world ready to manifest itself under circumstances of overcrowding and under no other conditions; but for all practical purposes this is begging the entire question. If the poison remain passive for years so long as certain conditions are absent, but becomes active or potent so soon as these conditions come into play, it seems fair to infer that the appreciable conditions, and not an omnipresent and indestructible poison, constitutes the primary cause of typhus.'

ALEX. COLLIE, M.D.

THE PROPHYLACTIC TREATMENT OF CHOLERA. By PROFESSOR LEBERT OF BRESLAU.

When cholera first appeared in Europe as an epidemic, it was for a long time believed that its spread could be arrested by shutting up the disease. But when it heedlessly leaped over the lines of isolation, a general search was commenced for specifics. The number of agents of this kind which have rejoiced in an ephemeral glory is almost legion. The conviction now gradually gained ground that we possess no specifics for most of the acute diseases, including that class which arises from infection, but that prophylaxis, hygiene, dietetics, and proper symptomatic treatment form the basis of our therapy of acute diseases. So long as this, laboriously acquired, had reference to diseases with a comparatively light mortality rate it entailed no disadvantage, as the method of expectation within rational limits furnished more favourable results by its avoidance of useless attack upon a disease improperly regarded as an enemy than the employment of the older perturatory methods.

But we come now upon a disease, in Indian cholera, which in its well pronounced, typical, and perfectly developed form slays the half of all persons attacked; indeed, even a greater number falls at the extreme limits of life and under unfavourable conditions. It may be readily understood how painful it must be for the physician at the bedside to reconcile himself to

the scientific fact of the absence of every certain and specific means of cure. But neither science nor practice have lost anything by the recognition of this melancholy truth. For whole decades of years the efforts of physicians have been unweariedly directed to prophylaxis, to the arrest of the disease in its first and lightest phases, and to the connexion which so often exists between a thoroughly scientific etiology and an enlightened system of practice; though very great obscurity still hovers about all these subjects, nevertheless much that is valuable has already been acquired, and we may even now look forward to the time when this fearful Indian guest, that has become only too often and too much at home among us, will be very much checked in its devastations. We are not to be led astray, however, because so much here, as in other departments of medicine, is mere probability, and we may in the meantime console ourselves with the reflection that our labours and struggles in this direction belong to the highest and noblest efforts of the human mind.

The treatment of cholera is divided into prophylactic and therapeutic, the first of which will occupy most of our attention.

We shall discuss here in order the questions of general international prophylactic regulations, of general local regulations both before and during an attack, as well as that of individual protection.

International Prophylaxis is directed chiefly to prevent as much as possible the importation of cholera and its dissemination. Notwithstanding the assemblies of eminent men especially versed in the subject of cholera, neither official congresses as that of Paris nor private meetings like the earnest and excellent cholera conference held at Weimar have hitherto essentially assisted an international protection. Absolute exclusion is impossible under the present conditions of transportation, and the attempts made up to this time, though always but imperfectly carried out, have furnished satisfactory results in no direction. During the last thirty years cholera has often regardlessly penetrated through double and triple military cordons. Sea-quarantine, too, which is much more easily effected, and by which vessels from infected or suspected places are detained from five to seven days, or, when there is recent infection, as from near harbours, for weeks at a time, has in no way fulfilled the expectations entertained of it. Still quarantine of vessels should be by no means abolished. Great movements of troops cannot always be avoided in cholera times for technical reasons, notwithstanding their decidedly injurious influence. The fact of evasion of the sanitary regulations for seclusion is no more of an argument against their employment than the lack of uniformity in the period of incubation and the transportation of cholera-germs by the air and by lifeless objects. A ship may propagate cholera-germs through lifeless objects even after a quarantine of weeks' duration. It is not necessary travel and commerce, therefore, but assemblies of crowds, as at popular festivals, annual markets, processions, pilgrimages, etc., which should be forbidden and arrested during the prevalence of cholera. If the injurious effects so very often proven of the great oriental pilgrimages of the Mohammedans as of the Hindoos continue to be denied by incorrigible miasmatisms, all the restrictive regulations now in force remain perfectly justifiable. When military necessities do not demand it, the most extreme care should be observed regarding the movements of troops from infected or strongly threatened regions,

* Extract from an article in Ziemsen's *Cyclopaedia of Practical Medicine*, from *Ohio Clinic*, August 22, 1874.

and every temporary summoning of the militia from places and regions in which cholera prevails should be avoided. If but little can be accomplished by seclusion, certain really humane regulations can be compelled as provision for medical assistance at border and railroad stations, and places where many persons congregate from different regions. This provision should have proper publicity, and attention should be commanded to the facts that arrivals from suspicious places must be treated for every form of diarrhoea, no matter how light, that an outbreak of cholera may be prevented in this way, and that physicians and remedies and means of transport are at the public service at these places. If now disinfection, which is to be specially discussed later, be early and thoroughly practised in these places, the evils may be reduced to a minimum degree.

Prophylactic Regulations for a Threatened Locality.—Though proper regulations for recreation may not be possible here, and though later isolation of a great number of patients cannot well be brought about, nevertheless great good can be accomplished by energetic measures with the first imported cases. Travellers affected with the disease and other strangers should be perfectly isolated at once, of course with every regard to humanity. The place for such patients should be well ventilated and thoroughly disinfected, and disinfection should be practised at all near railroad and mail stations in any way suspected, best along the whole line between the infected and non-infected places. The first residents of the place attacked should also be isolated as much as possible, and their localities should be thoroughly disinfected from the very start.

The threatened place itself should be subjected to the most extensive prophylactic disinfection possible. This is a point of special value, as such a disinfection is infinitely more valuable than the usually imperfect method commenced in the course of the epidemic and then mostly only poorly carried out. Cholera hospitals should be timely erected for the reception of patients, and suitable vaults for the evacuations constructed, that centres be not formed for the wider diffusion of the disease.

The outbreak of cholera should not be awaited before the greatest cleanliness is secured for streets, places, yards, and houses. All stagnant waters should be drained away, excrement removed from the vicinity of houses, the refuse of the trades, especially the easily decomposing garbage of butchers, regularly carried away under police supervision. The results are vastly better when privy-vaults are cleansed before than during an epidemic. Thorough disinfection should follow the emptying of the vaults and cloacæ. Especial attention is to be devoted to this point, as accumulation and decomposition of the contents of privies and privy-pipes, which is allowed to go on even to overflowing and blocking up, is absolutely incredible. It is high time that the attention of the authorities were directed to the privies, privy vaults, cloacæ and wells in an entirely different way from that hitherto. The wells are too superficial in many cities they are often damaged, especially in cold winters, they are not inspected, and are mostly only repaired when the pumps are at fault, so that the water does not flow from above, without regard to the good or bad quality of the water. The bad location of wells in the neighbourhood of privy-vaults, stables, etc., allows an easy communication, in time, with the products of decomposition and the organic substances of the soil water as well as the contents of

privies in their vicinity. During the prevalence of an epidemic, the wells may thus, by atmospheric emanation as well as by drinking, bring the dangerous germs after intense multiplication into abundant contact with the human organism. The more generally care is taken to secure a good water-supply by conduits from without with isolation and supervision of the whole system of pipes, the more will this auxiliary to the spread of cholera and many other diseases be combated. The conduit system has the great advantage that it permits a great increase in the number of wells and cisterns provided with constantly flowing water. Wells with water of notoriously bad quality should be closed up before an outbreak of cholera, and that without the least anxiety. The dwellings of the poorer classes should be thoroughly inspected at the right time, and all crowding, uncleanness, and bad ventilation, be at once attended to. Places of refuge to which the inhabitants of decidedly unhealthy dwellings could be sent before the outbreak of the disease are very much to be desired.

The sanitary police in supervision of food should inspect the markets with most particular care, and confiscate with penalties all unripe and decaying vegetables, fruits, potatoes, etc.; the same care should be taken that only meat and its products, especially sausages, of good quality are sold. Every commencing decomposition is to be religiously watched. The spirituous drinks should be closely inspected in regard to quality, acidity, adulteration, etc., and the same if available for milk. Cities threatened with cholera should be early supplied with ice. The benevolent institutions for better nutrition, as the soup-houses, with attendants, should be organised in time. The same is true for the service of nurses and for the appointment of civic and medical committees, etc. Care should be taken to secure an abundant supply of material, beds with their appurtenances, dishware, etc. The apothecaries should be strongly forbidden to sell emetic and purgative medicines without a physician's prescription. Disinfectants, of which more in detail later, should be laid in in such abundance as to be furnished to the poor free of charge. Care should be taken to provide dead-houses to which bodies can be carried immediately after death.

General Regulations on the Appearance of Cholera in a Locality.—So soon as cholera has broken out in a locality the people should be fully instructed as to the proper means of protection. The greatest emphasis should be laid upon the necessity of cleanliness, of good ventilation and good drinking-water, which should only be used after having been subjected to thorough boiling. There should be no hesitation in entering into details in explanation of these subjects. Attention should be called to the highly injurious effects of food and drink of bad quality or in commencing decomposition, and especially to the danger of diluting milk with infected water. On account of its dilution the milk should always be boiled. There should be no limitation of the accustomed food, when of good quality, a very common mistake of the pure theorists, who write cholera articles for the people. To throw suspicion on fresh ripe vegetables, while at the same time roast meat and wine is recommended, would sound like mockery and derision, were it not somewhat excusable on the grounds of thoughtlessness and ignorance of the manner in which the mass of the people live.

Most especial instruction should be imparted as to

the paramount importance of the prodromal diarrhoea, and the even higher necessity of proceeding against it as quickly and effectually as possible. The people should be taught also the easy transition of diarrhoea into cholera, the contagion from cholera excreta, and especially from cholera linen, for the disinfection of which rules will be given later. Easily comprehended information should be furnished also on the subject of disinfection. All cases of diarrhoea should be referred to physicians and medical bureaux, but warning should be given against the knights with 'sure cures,' as well as every form of charlatanism. A well-organised system of benevolence will regard not only the food, but also the sleeping-places, the beds, the fuel, etc., of the poorer classes, and secure the gratuitous provision of the tried remedies for diarrhoea, means of disinfection, etc. The number of physicians for the poor should be increased according to necessity and assistants as desired. Fixed bureaux for medical service, day and night, should be organised and provided with the necessary means of treatment and transport. Committees of physicians and civic officers should hold frequent consultations in common. House-visits among the healthy should be made also in wide extent by laymen for the purpose of instruction as to the means of quickly acquiring the proper remedies and treating the diarrhoea according to directions previously given (the visitation system). In manufactories, schools, infirmaries, barracks, prisons—in a word, wherever numbers are crowded together—daily inquiries should be made concerning health and *especially diarrhoea*, and action taken accordingly. This was a system that gave very favourable results in Paris in 1849. The sanitary police in control of the great numbers of individuals in all public or private situations may greatly assist in the general efforts by rigid supervision in regard to cleanliness, ventilation, drinking-water, food, privies, disinfection, transportation of the sick, vacation of pestilential centres, etc.

Cholera hospitals should be so situated as to be easily reached, but yet not in the midst of great centres of population. In middle and south Europe barrack-hospitals may also be erected. When possible, the lighter cases, as of diarrhoea and cholera, should be separated from the grave cases, and convalescents likewise. Transportation into the hospital is best effected by portable baskets, and care should be taken to secure the provision of a sufficient number of baskets, carriers, and attendants in season. Such provision will prevent the necessity of too great effort on the part of a few. These baskets likewise should be disinfected repeatedly, as also the dishes, night-vessels, beds, washing-rooms, etc., in the hospital. The utmost cleanliness and the most abundant and frequent ventilation are absolute necessities. The discharges must be quickly removed, mixed with carbolic acid or carbolised soda, and buried, or, according to Küchenmeister, mixed with sawdust and burned. Cholera patients are not to be put with other patients, and the cholera apartment should be as sequestered as possible, well ventilated, and carefully subjected to frequent disinfection.

If a centre of the disease be in process of development, or if it be already developed, all experience teaches that isolation is not only impracticable, but even useless. No matter how great the precaution, we only succeed in shutting up the wolf in the stall of the sheep. Vacation steps in now in lieu of isolation. When the anti-hygienic conditions are de-

cidedly bad, vacation may be effected by persuasion, or, if necessary, by force, which should be employed also, when the danger is great, even among the better classes. Of course care must be taken that the places of refuge are spacious and suitably constructed. Such was the case with the Klingenthal garrison in the Basel epidemic of 1855, where the results were excellent, as also with the music-hall in Zürich in 1867.

Besides the disinfection store-houses, whence disinfecting agents can be supplied to the poor free of charge, there should be large chambers where the washing, clothes, bedding, and other materials in contact with cholera patients can be subjected to disinfection under supervision of the sanitary police. But the materials to be purified should not be left long in heaps in the open air. When several cases of cholera have successively occurred in the same house, the wells, and especially the privies, should be closed up. But it is necessary in such cases to establish the fosses-mobiles system, as in Zürich in 1867, where these precautions seemed to have been attended with very good results. The contents of the night-vessels should be emptied into buckets in the halls and yards, and these buckets should be changed daily after thorough disinfection. If the privies cannot be closed they should be regularly disinfected under police supervision.

Disinfection of the linen before washing is absolutely necessary. This may be first accomplished in dry ovens or by fumes of sulphurous acid, then it should be thrown into boiling water and macerated before delivery to the washwoman, a point to which we shall return again.

When an epidemic is positively developed, regular daily bulletins should be published as to its exact status. Concealment or optimistic, therefore untrue, reports are decidedly injurious, while definite statements from the authorities quiet public apprehension. Dead-houses, to which bodies are to be carried as quickly as possible, should not only be properly arranged, but special attention should also be given to funerals. Great processions and long-continued ceremonies may be followed by injurious consequences. The authorities should also provide a sufficient burial corps.

(To be continued.)

REVILLOUT ON THE DIFFERENTIAL DIAGNOSIS OF DISEASES OF THE STOMACH.

In the *Gazette des Hôpitaux* for August 22, 1874 (no. 97), there is an article by Dr. Victor Revillout on the subject of gastric diseases. He complains, not without reason, that medical books are often too much like treatises on law—too systematic and too critical. Even Trousseau was often more of a critic than a clinical teacher, and Cruveilhier, in his last memoir on diseases of the stomach, was not free from this tendency. The latter was the first to describe simple ulcer of the stomach, and he maintained that it was generally possible to diagnose it from other gastric affections. Trousseau, in his clinical lectures denied this. In the works of both these great authorities, we meet with very rash assertions in close association with very precise and accurate descriptions. For example, Cruveilhier points out very precisely the characters of the pain which extends from the epigastrium to the spine at the same level, in gastric ulcer. But, whilst fully cognisant of the fact that the pain, both in its seat and in its character, closely resembles

that met with in gastralgia without ulceration, he sought in opium a criterion between the two affections. According to him, opiates promptly relieve the pain in simple gastralgia, whilst the gastric ulcer with gastralgia is unrelieved by these remedies. This was really a great delusion; for the truth is, that the pain, with or without ulceration, is sometimes quickly relieved by narcotics; whilst in other cases large doses prove ineffectual for this purpose. Trousseau was quite right in asserting this; but he was wrong in concluding from the failure of this test, that simple ulcer and gastralgia must necessarily be confounded together in practice. In the same way Cruveilhier, wishing to distinguish ulcer from cancer, asserted that in cancer there was no pain, properly so-called, originating in the nerves, but only suffering produced by muscular contractions, like those of the uterus in labour; depending upon the efforts of the stomach to overcome the obstruction set up by the tumour to the passage of alimentary substances. Although it often happens in cancer of the stomach that the pain is very slight, Trousseau had an easy task in showing that this was not invariably the case. But he went too far when he declared that simple ulcer and cancer were alike in their symptoms, so long as no tumour is discoverable. According to Trousseau, the only case in which we can make a differential diagnosis is when we discover a tumour in the parietes of the stomach. We shall see presently that such a tumour may sometimes originate in a simple ulcer of the stomach. Cruveilhier has, however, not recorded such cases; and Trousseau makes no mention of them. Are we to conclude, then, that no diagnosis is possible between different affections of the stomach? Are we always to be wandering vaguely in our practice, and never recognise the true nature of these affections at the bedside? The observation of a large number of hospital cases of stomach-affections leads Dr. Revillout to a very different conclusion. He says, justly, that the symptomatic physiognomy, or totality of symptoms, in cancer and in simple ulcer of the stomach, is in general extremely different. He gives two typical cases of cancer of the stomach. When the cancer is limited to the stomach itself we do not generally meet with dorsal pain, even when vomiting has been going on for some time, and the patients suffer acutely. This is true, at least for the major part of the duration of the disease.

For instance, there is a woman aged forty-six, in M. Potain's wards (no. 13, Salle Ste. Anne, Hôpital Necker), admitted July 9, 1874, who has been ill for six months, and exhibits in a very striking degree the characteristic straw tint (*la teinte jaune paille caractéristique*). This woman, before admission, vomited almost every day, sometimes twice a day, for several months; sometimes she merely vomited a glairy fluid, and sometimes the food she had taken. No other explanation of the cachectic colour, except the cancerous diathesis, could be entertained. Her feebleness and emaciation were even then very striking. Nauseated with everything, she could take no food without great effort, and whatever she took produced the feeling of a heavy weight on the stomach. Pressure in the epigastric region was very painful. But there was no painful spot over the vertebral column, nor in the intercostal spaces, and careful interrogation of the patient failed to prove that she ever suffered from any dorsal pain at any period of her disease.

Another patient, equally cachectic and equally emaciated, has been an inmate of La Charité Hospital (no. 8, Salle St. Ferdinand) since April 7, under the care of M. Rigal for M. Bernutz. This man, a mechanic, aged sixty-seven, has been ill for seven months, and has a tumour of considerable size in the epigastric region, on the right side. He has vomited ever since the appearance of this tumour. He had previously experienced very painful cramps in the stomach, and since the vomiting began these cramps have been almost continuous. He suffers day and night from his stomach. The pains are often so violent that he compares them to tearing asunder. Under careful régime of milk-diet with a little Bordeaux wine, and soup in the evening, the sickness has diminished, and for the last two months he has been almost free from vomiting, but his epigastric pains are almost as bad as ever. Yet this man has never had any pain in the back, and there is no point between the spinous processes sensitive to pressure. On this point his answers have never varied.

We are next presented with three typical cases of simple ulcers of the stomach.

In bed no. 13, Salle St. Vincent, at the Charité Hospital, under the charge of M. Woillez, there is a woman aged thirty-six, admitted on April 5, whose illness dates from January 10. Up to this year she had always enjoyed most perfect health. She said she had never had an hour's uneasiness, much less neuralgia or indigestion, or any tendency to illness. On the day named she breakfasted, with good appetite as usual, and went to work at the sewing machine in a house of business where she had long been employed, when all at once she fell down unconscious. Her syncope lasted half an hour, and on recovering she vomited a bowlful of black blood. Since then, she has always vomited more or less blood. These attacks of vomiting are preceded by acute pains, which generally last about an hour, and extend from the epigastric region to a point in the spine on exactly the same plane. She compares these pains to draggings which tear her flesh. Pressure on the epigastric region gives great pain; but she bears pressure on the spine very well, although the pain is referred there. It may be as well to remark, that since the hæmatemesis and the impaired nutrition, this patient has become highly nervous. She was not so before. There is now a certain degree of anæsthesia [*sic*] all over the body; there have been four well marked hysterical attacks; she complains of constant headaches. Lastly, there is a hyperæsthetic spot on the right side of the thorax, near the margin of the hypochondrium.

Another woman (in no. 16 bed, Salle Ste. Madeleine) at the same hospital, under the care of M. Brouardel, never having had hæmatemesis, is not hysterical. Otherwise her history resembles the case above. Her age is forty-three, she is a sempstress, and has now been ill seventeen months. Till then her health was excellent; living with her parents, who were fairly well off, she had never suffered privations. Her character is cool and collected (*posé*). Not easily impressible, she is not lightly moved to tears, nor is she noisy in laughter. She has always been regular, and free from nervous attacks. All at once, having breakfasted one day as usual, she felt suddenly an acute pain in her stomach and back, and then she vomited all she had eaten. After this day she could take no food without being

attacked sooner or later with vomiting, generally of food, sometimes of bile; the longer the vomiting is delayed, the more acute her pains. These often last the whole night, and she compares them to dragging, tearing, and sometimes to being cut with a knife. These pains extend from front to back, from the epigastric region, a little below the xiphoid cartilage, to the dorsal region, about the three first lumbar vertebrae. There is no other painful spot in the spine, either higher or lower.

At the Hôpital Necker (Salle St. Ferdinand, no. 11) we find an analogous case under the care of M. Delpech, admitted on July 28. The man is thirty-eight years of age, and is an engraver; he has been ill about seven months; he had always been quite well, till one evening after his dinner he vomited food for the first time. For some days the same happened after each evening meal. He thinks he did not suffer much then; but about a month after he vomited a basinful of blood. Then he felt acute pain, which extended from a point in the epigastric region about two fingers' breadth below the xiphoid cartilage towards a corresponding point in the back, about the first and second lumbar vertebrae. He compared this to the pain of a vice bruising the tissues. He was admitted first at the Hôpital St. Antoine, where he was treated by M. Cadet de Gassicourt for a simple ulcer of the stomach; he remained there about six weeks, during which time he vomited blood on several occasions; but under the influence of a milk-diet he so far recovered that he believed himself cured, and asked to be discharged to resume his business. Some days after the vomiting recurred, without blood however, and then he was admitted under M. Delpech's care, as described above. He was then dieted, and the vomiting ceased on the second day of treatment. In this case it is to be noted that there was not much pain so long as the vomiting was not severe. When it became so the pain, instead of being confined to the epigastrium almost invariably extended to the back.

The next case is one of ulcer of the stomach simulating cancer. We have had two distinct types of gastric disease in the cases previously narrated. In both there was vomiting, but one kind had no pain in the back; the patients complain of the stomach only, and there their sufferings are very acute, but there is no tendency towards the dorsal pain; these are the cases of cancer. The others have dorsal pain quite as severe as the epigastric, and on the same plane with this—or to speak more accurately, the two pains are really one and the same—and the patients compare the pain to dragging, tearing, or bruising; these suffer from ulcer of the stomach. Unfortunately all our cases are not so simple or so easy to diagnose. Sometimes, on the contrary, we meet with complications well calculated to lead us into error. But in such cases it is highly important not to lose sight of essential facts and first principles. When symptoms which appear contradictory are associated, they should at least cause us to hesitate and suspend our diagnosis, waiting for the judgment of time. We have a striking instance in the following case. On January 12, 1874, a woman, aged sixty-three years, entered the wards of M. Brouardel at the Charité (no. 22 bed, Salle Ste. Madeleine). She had for some time vomited black stuff, and shortly afterwards a hard, uneven tumour, about the size of a hen's egg, and not very sensitive to pressure, was discovered a little above the navel. Her stomach

was dilated, and her skin had an icterode cachectic coloration, like that of cancer. She stated that about four months previously, she had felt violent pains in the stomach. She soon began to vomit, first food, and then the vomit changed its character to a sooty or coffee-ground appearance. The gastric pain, starting from the epigastrium, and extending to the spine at the same level, had continued to grow worse. M. Revillout often asked the patient about this pain, and her answers were always consistent. The hæmatemesis continued; food was rejected soon after being taken, milk only being tolerated. Her emaciation increased rapidly; the sooty vomitings were more frequent; she was obstinately constipated; her appetite diminished, her weakness increased. From the beginning of July all the symptoms were exaggerated, and she died exhausted on the 21st of that month. At the necropsy, at which M. Cornil assisted, the pyloric end of the stomach was found indurated, and formed the tumour. The contiguous parts, epiploon, and transverse colon, were firmly adherent, and were much indurated. On opening the stomach, an ulcer was found at the pylorus, about 1½ inch in length, following the course of the pyloric canal. This ulceration was truly cup-shaped. The mucous membrane was lost at its edges, and its floor was formed by the transverse fibres of the stomach, which were themselves wanting at its deepest part, where the longitudinal muscular fibres became visible. This ulcer was solitary. Around it the hypertrophied walls of the stomach formed a tumour, which had no characters of cancer, either naked-eye or microscopic. It cut firmly, was hard, smooth and shiny, but no juice could be squeezed from it. In this case, the diagnosis of cancer of the stomach seemed reasonable. There was the tumour, and the icterode cachexia which are deemed so characteristic. It is true that hæmorrhagic [anæmic] cachexia may simulate the cancerous. But how could we explain the tumour? In an appendix to his memoir, read at the Institute in 1856, Cruveilhier speaks of a case lately noticed by him, *post mortem*, in which a simple ulcer of the pylorus had produced around it a thickening sufficiently marked to simulate a tumour on percussion. But no such case is considered in the propositions which summarise this memoir. For Cruveilhier as for Trousseau, a tumour meant cancer, and that only. Meanwhile this patient was not cancerous; her dorsal pain was therefore not exceptional, but confirmed the rule given above, for this, and this only, allowed the truth to be guessed at—that we had to deal with a simple ulcer, and not with cancer of the stomach. [The reporter thinks these cases so interesting in themselves that he has but slightly abridged them, or the comments of M. Revillout. He thinks, however, that he has met with exceptions to the universality of the dorsal pain, in cases of simple ulcer, proved to be such *post mortem*; indeed, with cases where there has been scarcely any pain at all.—*Rep.*] W. BATHURST WOODMAN, M.D.

KOLBE ON THE ANTISEPTIC PROPERTIES OF SALICYLIC ACID.

The physiological action of this substance has been little studied, though its physical and chemical properties are pretty well known. From the fact that it can be readily composed from carbolic acid and

carbonic acid, and that, on heating above the boiling point, it is decomposed into these two substances, Professor Kolbe, of Leipzig, was led to expect that, like carbolic acid, it would oppose processes of fermentation and putrefaction, and prove a good antiseptic. Along with Professor Thiersch, he made some experiments in this direction, which he has recently described to the Saxon Academy (See Dinger's *Polytechnisches Journal*, 2nd July number).

To ascertain how salicylic acid acted on ferments, he first dissolved some amygdalin in water, mixed with the solution a small quantity of the acid, and added an emulsion of sweet almonds. In a quarter of an hour, by which time a second mixture of almond emulsion and amygdalin, without salicylic acid, smelt strongly of bitter almond oil, the mixture containing the acid had not the least trace of such a smell. If the proportion of salicylic acid be very small, the smell will appear after some hours; but, with even a small quantity, no smell will be perceptible after twenty-four hours.

Mustard-seed powder, which in lukewarm water soon gives a strong smell of mustard oil, gives no such smell if a very little salicylic acid be previously mixed with it.

If a solution of grape sugar be mixed with a little salicylic acid (a thousandth at the most), yeast has afterwards no action, and a sugar solution already in fermentation ceases to ferment when a small quantity of the acid is added.

[Details of such an experiment are given.]

Again, some Leipzig beer of excellent quality was divided among several wide glass beakers (1,000 grammes to each), and kept fourteen days at a temperature varying between 68° and 75° Fahr., the vessels being covered with loose paper. To one vessel was added (and mixed with the beer) 0.2 gramme of salicylic acid; to a second, 0.4 gramme; to a third, 0.8 gramme; to a fourth, 1.2 gramme; in another glass the beer remained unmixed. This last began at the end of the second day to deteriorate, and became coated with a layer of fungus. In the vessel with 0.2 gramme of salicylic acid, the fungus vegetation commenced on the third day; in the vessel with 0.4 gramme, on the fifth; in that with 0.8 grammes on the tenth; while the 1,000 grammes of beer to which 1.2 grammes acid had been added, did not even after twelve days show any fungus vegetation. Thus a thousandth of salicylic acid, added to beer, suffices to preserve it from injury through fungus growth.

Next, fresh and pure cow's milk, with 0.4 per cent. of salicylic acid added, and left in an open vessel, at a temperature of 64.4° Fahr., was thirty-six hours later of curdling than an equal quantity of the same milk beside it, which was without salicylic acid. The addition of a little more salicylic acid delays the souring and coagulation still longer. The milk continues to taste well; the taste of the small amount of acid is not perceptible.

Some newly passed urine was divided into two portions, and kept several days in separate vessels. A little salicylic acid having been added to one portion, this was found on the third day still clear and free from the smell of ammonia; while the other portion was already far gone in decomposition and smelt strongly.

Fresh meat, rubbed with salicylic acid, will keep for weeks, in air. The author prepared large quantities of beef and mutton with the acid, put them in a

large covered vessel, and a month afterwards he found them still quite fit for cooking. Most of the salicylic acid can be removed by washing, before the use of the meat. The remaining portion has a not unpleasant sweet taste, but it is hardly perceptible.

Professor Kolbe further states that he put hen's eggs, fresh laid in March and April, in an aqueous solution of salicylic acid, and let them lie about an hour in it. After drying, in air, they were laid in a box filled with chaff; in a second box was placed similarly a fresh egg, which had not been impregnated with acid. The eggs will be examined after six, nine, and twelve months have passed, and the results communicated.

Professor Thiersch made some experiments in the Leipzig Hospital as to the antiseptic action of salicylic acid, and its use in surgery. He says that when strewn (either by itself or mixed with starch) on contused wounds not yet cleaned, and on scurfy gangrenous surfaces, salicylic acid destroys, for a long time, the putrid odour, without any inflammatory action of importance. In solution of one part of salicylic acid, three parts of phosphate of soda, and fifty parts of water, it favours the coating over of granulation-surfaces. As to its action on fresh wounds, the following data are communicated. During the operation, the wound is kept under a spray cloud of salicylic acid in water (one in 300). The dressing of the wound consists of wadding, impregnated with salicylic acid in the crystallised state. The wadding is moistened with salicylic acid in water (one in 300), as also the strip of muslin by which it is held. Afterwards, a continuous dripping of the acid solution on the bandage, about eight drops in the minute, is maintained. After an amputation of the femur on April 27, under such treatment, the patient experienced no pain, nor swellings, nor fever. The first renewal of the dressing was on the sixth day. The secretion in the wound during these six days was without smell. With equally good results, Dr. Thiersch performed some other amputations. He is of opinion that salicylic acid has all the advantages of carbolic acid, without its inconveniences.

ALEX. B. MACDOWALL.

MEDICINE.

ALLBUTT ON A CASE OF MEDIASTINAL SARCOMA, SIMULATING 'CALLOUS MEDIASTINO-PERICARDITIS.'—In the *British Medical Journal* for September 5, 1874, Dr. Clifford Allbutt has recorded a very interesting case of mediastinal sarcoma, which in its clinical features and *post mortem* appearances presented some resemblance to the cases of 'callous mediastino-pericarditis,' described by Kussmaul in the *Berliner Klinische Wochenschrift*, (nos. 37, 38, 39, 1873), and of which an abstract was given in the LONDON MEDICAL RECORD, December 17, 1873. The patient was a girl, aged sixteen, of delicate appearance, who had had no previous illness, save an attack of small-pox when young. A sister had died of phthisis, aged twenty-one, but her parents were alive and well. The girl caught a cold on 'Shrove Tuesday,' which was followed by cough and shortness of breathing. For a month previously to her admission, she could not lie down on account of dyspnoea and palpitation. She had had no pain. On admission the superficial veins of the neck were prominent, and she had the aspect 'of one suffering under the

pressure of an acute disease ; she had the præcordial anxiety, the pallor, the distress and the fear of movement which are often seen in pericardial effusion. There was considerable dulness in the middle of the chest, but the distribution of the dulness was not like that of pericardial effusions. 'Taking the base line of dulness from the lower edge of the liver and heart, it extended upwards all over the front of the chest, leaving only a triangle of resonance at the upper and outer corners. The two outer thirds of each clavicle might be taken as the upper side of an equilateral triangle of comparative resonance on each side. All beside was dull, and the dulness reached about an inch beyond the mammary line on each side. On the left side of the chest, however, there was another district of dulness continuous with the former, and clearly corresponding to a small pleuritic effusion. The pulse was small, rapid, irregular, and sometimes intermittent. The respiration was very shallow and frequent ; so much so, that it was impossible to say whether inspiration had any effect upon the fulness of the jugular or upon the radial pulse.' The left pleura was tapped, and fourteen ounces of clear fluid withdrawn by the aspirator. The patient, however, died fifteen minutes after the operation. The 'paradoxical pulse' was not noticed, on account of early death. At the necropsy the following were the appearances. 'There was enormous dilatation and thickening of the pericardium, due to a firm yellowish homogeneous-looking growth, occupying the anterior mediastinum and reaching above to the thyroid on the left, and to the diaphragm below on the right. The chief mass of the tumour was situated in front of and around the base of the heart, completely embedding the great vessels at the root of the neck and the arch of the aorta, and closely adherent to them, but not seemingly contracting their calibre. The tumour blended insensibly with the pericardium. In front it had evidently been adherent to the sternum and costal cartilages. Below, the adherent diaphragm showed several nodules of similar structure. The enlarged pericardium formed a nearly globular sac, flattened below where it rested upon the diaphragm, and about eight inches across. Its lining was more opaque than natural. The heart was small, flabby, and pale. Along its anterior borders and near the base were several nodules of the new growth, on incision evidently infiltrating the muscular tissue. The lungs, which had evidently been laterally displaced, were small and almost airless, with the exception of their apices. Around their roots, and extending along the vessels and bronchi, and the edges of the lobes for a short and variable distance, was the same sort of tissue as in the mediastinum. The microscopic appearance of the growth was that of small round cells, with no fibrous stroma, and very little intercellular substance. A section from a nodule upon the heart showed the same material infiltrating the muscular fibres ; and in one from the root of the lung, the pulmonary tissue was infiltrated with similar small cells.'

[Dr. Allbutt's case, in the opinion of the reporter, corresponds pretty closely with the class of cases designated by the terms lymphadenoma, lymphosarcoma, or Hodgkin's disease. A very similar case to his is minutely described by Dr. Risdon Bennett, at p. 148 of his book *On Intrathoracic Growths*, and one not unlike it has come under the notice of the reporter and is published in the *British Medical Journal* for September 19, 1874. Dr. Allbutt has omitted to

mention the condition of the lymphatic glands, spleen, etc., in his case, and it would be interesting to know the state of these organs. In the reporter's case there was enlargement of the spleen and mesenteric glands, in addition to the mediastinal growth. The case was also complicated by bloody pleurisy.—*Rep.*]
J. B. BRADBURY, M.D. (Cambridge).

EYSELEIN ON HICCUP OF NEARLY FOUR WEEKS' DURATION AT THE COMMENCEMENT OF CANCER OF THE STOMACH.—The *Berliner Klinische Wochenschrift*, no. 30, contains a paper by Dr. Oscar Eyselein, of Blankenburg, on this symptom. The patient, a master bookbinder, aged forty-six, had both parents living and healthy, and his grandparents both reached nearly ninety years of age. His four sisters were healthy. He had suffered since October, 1872, from a febrile attack of bronchial catarrh, with much expectoration, and considerable disturbance of his digestive functions. These symptoms lasted, with partial recovery, till the spring of 1873, when his general health became satisfactory, and the catarrhal symptoms almost entirely vanished. There were no other objective signs of disease. His recovery was slow, although he took a good deal of out-door exercise. At the end of May, without any obvious cause, he was attacked with hiccup ; at first a simple heaving, afterwards, as the patient phrased it, 'in double strokes.' This lasted all day, all night, and the next day, and was not relieved by an opiate which he took for the purpose. As he suffered much pain, and the spasmodic action of the diaphragm intensified this, he tickled his throat, believing that, the stomach being the offending organ, vomiting would relieve him. After getting rid of a good deal of food, the hiccup ceased for a short time. It recurred in the evening, and Dr. Eyselein ordered him morphia and cherry laurel-water, without relief. The moment the patient sought to appease his hunger, the hiccup returned violently, and was only stayed for a short time by fresh vomiting of a little food and slimy mucus. The intervals between the hiccup were from ten minutes to half-an-hour ; and, however little nourishment was taken, or whatever its quality, it regularly made him hiccup. All the drugs tried, chloral, bicarbonate of soda, Ems water, effervescing powders, mustard plasters, tartar-emetic, cannabis Indica, etc., were quite ineffectual. In consultation with a colleague, on the fourth day, he was ordered strychnia, with no better success. Ice swallowed in small pieces, and the application of cold compresses, and the hydropathic 'pack' to the neck and stomach, were equally unsuccessful. Faradisation of the phrenic nerve stopped the hiccup immediately on the first application, but afterwards produced no effect. On the seventh day his 'cramps' were very violent and painful, and he was pronounced to be 'delirious' by the bystanders. He sometimes lay for a long time with open eyes in a dreamy condition. [Delirium of inanition?—*Rep.*] Then he had violent choking fits, with a peculiar whistle, his teeth being firmly clenched. By patting his back and pressing the jaws forcibly together he would recover consciousness for a while and feel better. The hiccup lasted 9½ hours on this day, and only ceased after he was made sick ; every particle of food and drink had to be got rid of before the hiccup would stop. Altogether, in twenty-four hours six only were free from this distressing symptom, for night only brought slight relief. His general health could not fail to be impaired ; he would not stop in bed, and was always

tired and exhausted. All the next week he continued in the same state; the hiccup never ceased spontaneously, nor could he suppress it, and a strong effort to do so brought on a violent shivering. As his finger, which had scratched his fauces till they bled, no longer sufficed to cause vomiting, he seized a stick and pushed it down his throat, thereby causing vomiting and temporary relief. Cold and profuse sweats set in. At the beginning of the third week carbolic acid was ordered, but ineffectually. This week passed like the preceding. As before, he could never take more than the yolk of one egg and a morsel of bread at 5 A.M. Anything else, and even the same food taken at other times, or only a quarter of an hour later, would be rejected. Milk was retained longest—for half an hour. Before the hiccup ceased, a brownish yellow mucous fluid, of somewhat clotted appearance, was vomited. From this time he kept out of doors as much as he could, walking as far as his strength allowed. His sad condition never changed. At the beginning of the fourth week, he seemed to derive much pleasure from a few whiffs of tobacco. In his former illness he could neither taste nor smell, except very putrid paste. Like many other old bookbinders, he said he had lost his sense of smell; partly perhaps from coal-dust and from the use of putrid blood, alum, and the hot iron in their art. At a later period, he again lost his smell. He was now allowed to smoke, but the hiccup recurred, and never ceased till he vomited all the food taken. It always stopped after a very powerful 'heave' of the stomach. Then he smoked only in the free intervals, and slept well for the first time for weeks. In the afternoon the 'strokes' of the hiccup were weaker, and ceased after a dose of nicotin the next morning. To clench success, iodide and bromide of potassium were given in solution, but seemed to aggravate his former symptoms. However, the yolks of two eggs and a double quantity of bread was now retained. Hunger and thirst were now extreme, and he gratified them, notwithstanding pain; taking one and a half litre (over a quart) of iced water at a draught. The bowels were relieved pretty regularly every five or six days, the stools being semi-solid. The next few days the pauses were longer, the hiccup more easily controlled; but even when improving, the least excess in eating or drinking renewed the hiccup, and necessitated emptying of the stomach. During the next four weeks any exposure to cold brought on shiverings, and cramps in his stomach. He was advised change of air, but returned in three weeks little better or even worse. He now looked cachectic, his colour was a pale grey, and his features were sunken. Then, for the first time, inspection of the bare thorax revealed, in the right supraclavicular region, besides increasing emaciation, a swelling towards the right ear, which was certainly not present when Faradisation was tried. This was found to equal the size of a fist, and to consist of a mass of glands, varying in bulk from the size of a pea to that of a canary bird's egg. They were not painful. Deeper glands were also involved. A firm gland about the size of a pigeon's egg in the right axilla was found to have been noticed some three years before, after a violent squeeze under the arms. It now seemed probable that these deep glands, by their progressive growth, had produced irritation of the phrenic nerve. They had probably received some check, and ceased to enlarge, and grew in another direction. In any case it seemed probable that there was carcino-

matous infiltration of the walls of the stomach, and of the brachial and cervical glands.

About August 23 his gastric symptoms were intensified. The epigastric tenderness prevented any accurate physical examination. Local anæsthesia by Richardson's apparatus (chloroform 4 parts, absolute alcohol 1 part), relieved his pains. The urine showed a trace of albumen. From this time he grew weaker and thinner, and more cachectic. For a short time he ate whatever he fancied, apparently with impunity. He died at last, worn out, on January 17 of this year. There was no *post mortem* examination. [The sequel of the case shows that there was serious organic mischief, probably carcinomatous, although the facts do not exclude syphilis. Still the reporter thinks it a pity that, in so severe a case of hiccup, complete rest to the stomach, by means of nutrient enemata, the hypodermic use of morphia and atropin, and the inhalation of nitrite of amyl and chloroform, do not appear to have been tried.—*Rep.*]

W. BATHURST WOODMAN, M.D.

SIMON ON HÆMOPHILIA.—Simon (*Recherches sur l'hémophilie*, Thèse de Paris, reviewed in *Gazette des Hôpitaux*, no. 96.) reporting some cases of hæmophilia, speaks of the pathology of this disorder. He does not allow any material change in the vessels, as this will not explain the temporary disappearance of the hæmorrhagic diathesis nor its permanent disappearance in advanced life. He sustains the hypothesis, first set forth by Cochrane, Otte, and others, of a disturbed innervation, causing a paralytic dilatation of the vessels which favours their rupture. Further, bleeders are very subject to rheumatism [this is by no means the same as acute rheumatism. *Rep.*] and rheumatism is a common complication of chorea, a nervous affection. On these grounds Simon is inclined to believe that hæmophilia is only another expression of a rheumatic diathesis. [There seems to be very little new or important in the thesis.—*Rep.*]

J. WICKHAM LEGG, M.D.

SURGERY.

MARTINEAU ON TUBERCULOUS ULCERATION OF THE ANUS AND OF THE LEFT BUTTOCK IN A PATIENT SUFFERING FROM PULMONARY PHTHISIS AND TUBERCULOUS ULCERATION OF THE FAUCES. M. Martineau exhibited to the Société Médicale des Hôpitaux (*L'Union Médicale*, July, 1874) a model representing a tuberculous ulceration of the left half of the anus and the corresponding buttock.

The patient stated that the ulcer had been preceded early last April by an itching pimple; soon numerous pimples developed, and the itching became very severe; to this itching there followed a sharp persistent pain, increased by the passage of feces—which since the month of March had been liquid. At the beginning of May he was seen by Dr. Martineau, who thus minutely describes the character and condition of the ulceration. On the left buttock was an ulcer irregularly round, having its point of commencement in the rectum on the left side of the intestine, and extending to the upper border of the sphincter. The edges which limited the ulceration on the buttock were slightly projecting, not cleanly cut, and gradually merged themselves in the centre of the ulcer. The margin of the ulceration was slightly bluish in colour, and presented numerous nipple-shaped projections, or multiple yellowish

granulations, about the size of a pin's head. Some of these granulations were in process of destruction; they were replaced by an ulceration which, gradually extending itself superficially and deeply, became mingled with the central portion of the ulcer, which was grey and not bloody; it presented also numerous nipple-shaped projections, yellowish, and separated one from the other by alveoli, giving the ulceration the aspect of areolar tissue, and also by fissures, notably two which, starting from the circumference, were prolonged into the interior of the rectum, extending to the upper part of the sphincter. The antero-posterior diameter of the ulceration measured about $1\frac{1}{2}$ inches, and from without to within it was about $2\frac{3}{4}$ inches. The ulceration appeared to affect only the skin and superficial parts of the dermis. The ulcer itself was soft and pliable, and had no hardened basis. Around the ulceration on the left buttock, in the sulcus, and on the right buttock, there were eight or ten prominent tubercles, which were not painful. (Two of these tubercles had recently commenced to break down.) The external glands in the groin were slightly tumefied, but not painful.

Dr. Martineau considered that the tuberculous nature of the ulceration could not be doubted. It resembled exactly the tuberculous ulceration of the tongue described by Dr. Féréal. There was not the slightest evidence of syphilis in the patient. If any thing were wanted to set the question at rest, it might be found in the fact that the patient had all the physical characteristics of pulmonary phthisis. He had constant cough, great emaciation, diarrhoea, is aphonic, had tubercular ulceration of the fauces, and in all probability of the larynx also. No treatment had availed to arrest the ulcerative process, but the pain was much relieved by the use of a lotion composed of one part chloral hydrate to one hundred of water.

In the discussion which followed, Dr. Féréal agreed with the author in his diagnosis. He had seen several precisely similar cases, and cited two as having occurred last year at the Maison de Santé, and another at the Hôpital St. Antoine.

[The reporter has observed ulceration of the rectum, anus, and adjacent parts, to which the description of Dr. Martineau would most accurately apply; but he has never seen in association 'tubercles' developed in the buttocks or elsewhere in the neighbourhood of the ulcer, nor the question as to the tuberculous origin of the ulceration so decidedly and unmistakably answered.—*Rep.*]

WM. ALLINGHAM.

TILLAUX AND OTHERS ON ACUTE RANULA.—At a meeting of the Société de Chirurgie held on June 3 last, M. Tillaux read a note upon acute ranula (*Le Progrès Médical*). Hitherto he had considered that the obliteration of the ducts of the sublingual glands, and the accumulation of the liquid contained within them, accounted for their formation. But this is not sufficient to explain the origin of ranulae which arise suddenly. M. Tillaux had seen a man who went to bed perfectly well at ten o'clock at night, and at three in the morning he awoke with a large tumour under his tongue. A woman who was going down stairs, and another who was sitting by the fireside, were attacked equally suddenly. These tumours were encysted, and contained a clear, thin fluid, very like saliva. M. Méhu, who analysed it, could not pronounce exactly upon its nature. Some authors consider that these ranulae

are produced by the exaggerated dilatations of Wharton's duct; but this duct is far from being very dilatable, as M. Tillaux has proved by direct experiment. He has injected and inflated it with considerable force, and the utmost size it attained was that of a crow-quill. When the pressure was increased, the duct gave way. But in the neighbourhood of the duct there is a cavity capable of containing a certain quantity of liquid—viz., Fleischmann's bursa, which M. Sappey said he had been unable to detect. M. Tillaux exhibited two specimens in which this synovial sac was very perceptible. It is triangular, situated between the frænum and the genio-glossus muscle, which it penetrates to the depth of about 27 millimètres. Wharton's duct is separated from it only by a very thin membrane. If, then, there was an opening from this duct into the bursa, it would be sufficient to produce a ranula. But Wharton's duct is very tough; it is necessary, therefore, to suppose that, while an obstruction prevents the flow of saliva, there is some degeneration in the walls of the duct which determines a rupture.

M. Dolbeau did not consider that M. Tillaux's theory was sufficient to explain certain forms of sudden ranula. Four years ago M. Dolbeau had seen a lady who was threatened with suffocation in consequence of a sudden tumefaction of the floor of the mouth. Spontaneous resolution took place, but the patient died shortly afterwards from congestion of the lungs. A market porter applied for advice with a retroverted tongue, under which was a large tumour. Wharton's duct was free. The tumour disappeared rapidly, but a small submucous abscess was formed. M. Tillaux's suggestion does not explain the spontaneous dispersion of the swelling.

M. Duplay did not believe that the fluid contained in a ranula was always analogous to saliva. It rather resembled the liquid of mucous oedema. Nor is the tumour always encysted. M. Duplay quoted cases in which Wharton's duct was much dilated, and constituted a true ranula. M. Tillaux ought to have experimented upon a diseased duct if he wished to ascertain its degree of dilatability.

M. Lefort did not believe in the existence of a serous sac beneath the tongue.

M. Tillaux had examined histologically the membrane which lines this cavity. It exhibits all the elements of a serous membrane. The principal object of his communication was to demonstrate the existence of this membrane, and it seemed to him that it explained certain cases of ranula. The examples cited by M. Dolbeau were not of the same kind as his own. His explanations applied only to encysted ranulae arising suddenly, and containing a clear, thin fluid.

W. FAIRLIE CLARKE.

LOBECK ON CONGENITAL UMBILICAL HERNIA.—At a meeting of the Dresden Medical Society, on July 26, 1873, Dr. Lobeck (*Berliner Klinische Wochenschrift*, July 28) showed on the dead body of a child, fourteen years old, a healed congenital umbilical hernia, which was about the size of a small apple, and formerly contained loops of the small intestines protruding through an opening in the abdominal walls of about the dimensions of a crown-piece. This had become closed by exuberant granulations from the peritoneum and from the margins of the sac, which former presented on its surface a stellate

cicatrix. * The enormously enlarged right kidney, three or four times its natural size, was especially considered the cause. W. C. GRIGG, M.D.

OBSTETRICS AND GYNÆCOLOGY.

VERNEUIL ON BLOODLESS EXTIRPATION OF TUMOURS OF THE VULVA.—M. Verneuil (*Gazette Hebdomadaire de Médecine et de Chirurgie*, June 5, 1874) relates the following six cases.

Case 1. An epithelioma of the left labium majus and corresponding vaginal wall was treated by the écraseur, the chain being applied first by aid of a curved trocar and cannula plunged under the growth. The chain had to be applied in four different directions, and the operation, though successful and bloodless, occupied forty-five minutes. Cicatrization was complete in a few weeks. Eighteen months afterwards, there was no sign of return; and an enlarged inguinal gland had disappeared.

Case 2. An epithelioma occupying nearly the whole length of the left labium was removed in a few minutes by a double-chained écraseur, invented by M. Verneuil.

Case 3 was one of very large epithelioma of the superior commissure of the vulva, implicating the mons Veneris, both labia, and the region of the clitoris. A groove was first marked out round the tumour with the galvanic-cautery knife, and then the operation was completed by two écraseurs, worked simultaneously. The operation was successful, but a return of the disease carried off the patient in seven months. So completely was M. Verneuil satisfied with the galvanic knife here, that in the three other cases he employed it alone.

Case 4. was one of epithelioma of the left labium majus. The growth was drawn forward by the left hand, while a groove was traced round it with the galvanic-cautery knife, and then the base was separated. The knife (wire) was kept at a dull red-heat, and the operation only occupied four or five minutes—a period sufficiently long to complete it without loss of blood or use of ligatures. The patient did well at first, but eventually died from extensive gangrenous erysipelas.

Case 5. In this case, one of enormous elephantiasis of the labia and mons Veneris in a girl, aged twenty, a groove was again traced round the growth with the galvano-cautery; but, as it had been used for the previous case, the fluid in the battery became exhausted, and M. Verneuil tried to complete the operation with the écraseur. He found, however, the skin so hard and the progress so slow, that he was afraid of breaking both chain and rack, and had the battery re-filled, and finished with the galvano-cautery. To fix the chain of the écraseur, it was necessary to cut a little with scissors, and the free hæmorrhage showed what might have been expected if the whole had been a cutting operation. The time occupied was forty-five minutes. He makes the following remarks on this case. 1. It is quite possible to follow easily with the eye what the galvano-cautery knife is cutting. Here he was even able to work more slowly when dividing small vessels. He even thinks it easier than when the parts have acquired a general red hue from sponging during a cutting operation. 2. Vessels divided by the cautery can still be ligatured, and if over a certain size require to be. 3. He alludes to the hæmorrhage when the scissors were used a little; also 4. To the hard-

ness of the growth, and the danger of breaking the écraseur. 5. The bath of the battery can be refilled in a few minutes, if the whole be first plunged into a pail of cold water to cool it. The edges of the wound were partly drawn together by silver sutures, and a dressing of wool dipped in alcohol and carbolic acid used. The operation was done on April 1 (the same day as Case 4), and the patient was quite well on May 18, never having had a bad symptom.

Case 6 was one of erectile venous tumour on the labium of a girl aged six. As it was difficult to surround the growth with the cutting loop of the cautery, M. Verneuil used the knife (cautery) and made a regular dissection, the so-called knife being a fine wire of platinum, heated to a dull red. Two or three minutes completed the operation. A simple water-dressing was used, and the patient had a narrow escape from a very severe attack of erysipelas, with abscesses, etc., but ultimately recovered, merely a small linear cicatrix remaining, and the labium being natural in shape.

In some concluding remarks, M. Verneuil points out that there is no greater immunity from erysipelas, pyæmia, and like diseases, after these bloodless operations than when the knife is used. An epidemic of erysipelas was raging at the time when the last three cases were operated on; but he cannot admit contagion in the case of the little girl, who was a private patient, and whose wound he did not touch, the mother dressing it.

[M. Verneuil acknowledges that the discharge in the last case was putrid, and it is to be noted that of the three the one dressed with an antiseptic dressing escaped the disease. With regard to the other cases, they are very interesting and instructive, and amply support M. Verneuil's advocacy of the galvano-cautery. Few will be disposed to differ from him who have tried it in like cases.

In the cases the reporter has seen, however, he cannot say it was quite so easy to follow the wire and see what it was cutting as M. Verneuil has found it.—*Rep.*]

M'RAE ON VESICO-VAGINAL FISTULA, WITH SUBSEQUENT CONCEPTIONS. — Dr. A. E. M'RAE (*Edinburgh Medical Journal*, August 1874) gives a case which illustrates the dangers that beset a pregnant woman, when she has already been the subject of a successful operation for vesico-vaginal fistula.

Mrs. C., aged twenty-one, after a labour lasting forty-eight hours (from impacted head in the brim of the pelvis, and finally a forceps delivery), became the subject of a vesico-vaginal fistula. The labour was in October 1871, and in December the fistula was cured by operation by Dr. Joseph Bell in the Royal Infirmary, Edinburgh. Early in 1872 she again became pregnant, and in September, after being in labour twelve hours, was seen by a medical man, who called in Dr. M'RAE in consultation. Pains were constant and severe. On making a vaginal examination, Dr. M'RAE found a tumour about the size of an orange far up on the anterior wall of the vagina, its lower edge being continuous with the anterior wall of the vagina, and the upper edge attached to the posterior wall and continuous with the body of the uterus; there was extreme tension of all the tissues, but no os could be detected, only a slight depression, with an annulus of dense tissue situated about half an inch from the union of the tumour with the anterior vaginal wall. It was

evident that the cicatrix consequent on the fistula and operation for its cure had contracted so much as to obliterate the anterior *cul-de-sac*, thus seriously diminishing the dilatable tissue. The patient being in a very exhausted state, sedatives were administered, the bowels cleared, and she passed a good night, and no interference was deemed advisable till the following night at 11 P.M., when she was chloroformed, and then something like an os with a tense membrane stretching across it was made out. Attempts to rupture this failed, but eventually a small slit was detected at its upper edge, and Dr. M'Rae introduced the blade of a pair of curved scissors, and divided the cervix in two places, cutting only into healthy tissue and avoiding the old cicatrix. The membranes at once filled the opening, and little or no hæmorrhage occurred. The labour was now urged on by ergot, but the head again became impacted, and the aid of the forceps was required. Hour-glass contraction and retention of the placenta followed, but eventually she made a good recovery. In August 1873 she was again in labour, the os being palpable, but again entirely occluded. After careful watching for forty-eight hours it dilated to the size of a florin, and was fully dilated by manual dilatation. The head again stuck, and forceps had to be used. The child, a full-grown male, died immediately after birth. In March, 1874, the patient being again pregnant, and having pains in abdomen, feared another miscarriage, and sent for Dr. M'Rae. On examining *per vaginam* he found the canal only two and a quarter inches long; there was no depending cervix, and no anterior or lateral *cul-de-sac*. A hard tumour extended from just above the os urethrae to the posterior *cul-de-sac*; a very narrow os, omitting the nail of the index finger, could be felt, and this eventually opened to a size to admit a sixpence, and there was a little hæmorrhage, but with rest, etc., it passed off, and the patient is now going about well.

[This is an interesting case, but rather as a pathological curiosity than as one of much clinical value. Seldom, indeed, would one be likely to meet with such a variety of peculiarities in a single case:—narrow pelvis? (this is implied, but not stated); vesico-vaginal fistula, or rather the results of it; and then the peculiar membrane occluding the os, not merely in the first labour after the cure of the fistula, but recurring again and again. It would be a more complete and therefore more interesting case, if Dr. M'Rae had told us what the extent of the original fistula was, and whether Dr. Bell had to cut into the os or cervix; also whether any menstruation occurred during the operation and the following pregnancy.—*Rep.*] J. KNOWSLEY THORNTON.

KEHRER ON RETRACTED NIPPLE.—Professor F. A. Kehrer, of Giessen (*Archiv für Gynäkologie, and Birmingham Quarterly Medical Review*, July, 1874), states that in some cases, where the nipple is either entirely or nearly under the level of the areola, it can be so brought into prominence by the vigorous action of the child that the latter is able to extract the milk; but there are others in which the retraction is more marked, and which one might aptly term cases of *mammilla circumvallata*, when it is impossible for the child to seize the nipple without surgical interference. In these we have a crater-like cavity surrounded by a wall, in which the short nipple lies concealed at a depth of a centimètre and a half, and from which the strongest efforts of the child are in-

sufficient to draw it. Sometimes the opening into this cavity is so narrow that the nipple could not be drawn out of it even if the child were strong enough, and to this is added the swelling of the parts by the mechanical irritation of the fruitless sucking of the child.

By a simple plastic operation, consisting of the excision of the ring surrounding the nipple, the *mammilla circumvallata* may readily be converted into a *mammilla prominens*, aided by artificial exhaustion of the breast. For this purpose two incisions are made, the upper corresponding to the edge of the cavity and uniting at an acute angle with the lower, at each side at the lateral and median margin of the areola. The skin and subjacent tissue are then raised in a direction towards the nipple, care being taken to avoid the milk-ducts, until the *mammilla* is isolated all round. The edge of the skin-flap thus raised is then to be removed for one or two millimetres in breadth, the hæmorrhage being controlled by cold sponging, and the opposing edges of the wound brought together. In order to avoid tension, it may be advisable to undercut the outer edge of the wound. The wound, when closed, is somewhat oblique, and encloses the nipple, as in a circle. Its after-treatment demands nothing special. After it has healed, the nipple will be found to be on a level with the surrounding skin, or even to be somewhat prominent, and this improvement may be increased by the use of exhausting glasses.

BILLE ON LUXATION OF THE RIGHT SACRO-ILIAC SYNCHONDROSIS.—Dr. Bille exhibited before the Dresden Medical Society on July 5, 1873 (*Berliner Klinische Wochenschrift*, July 13, 1874), the pelvis of a young woman, aged twenty-two, in which this accident had happened. She was stated to have been seventy-nine hours in labour, and as far as could be gathered, she was delivered by the forceps. She had endocolpitis and endometritis during the puerperal stage; but on the tenth day she felt well enough to return to her home. Shortly after her return she began to experience intense pain over the right iliac joint, which compelled her to re-enter the hospital. On admission, all the organs were found healthy with the exception of the uterus, which was subinvolved and very sensitive. Any movement of the right thigh caused crepitation to be heard and felt over the hip-joint. Abscesses formed, opening into the hip-joint and above Poupart's ligament. In the seventh week, she sank from the exhausting drain of pus. The necropsy showed several fistulous tracts leading from Poupart's ligament to the sacro-iliac joint, also infiltration of pus into the sheaths of the deep muscles of the thigh, with separation of the periosteum from the neck of the femur.

The articular surfaces of the right sacro-iliac synchondrosis were roughened and carious, the bones being separated about two lines from each other. The surrounding soft parts were infiltrated and discoloured. The other parts of the pelvis were all healthy. Dr. Bille was induced to believe that the pelvis was quite normal, but the child was disproportionate; but he did not suppose that it (the child) need have separated the joint, and so set up inflammation. It was probably a distinct affection coming on incidentally afterwards. Dr. Krüger combated this view, maintaining that it arose most likely through the foetus being left too long in the second stage, which set up mischief in the joint. This view was not accepted by the Society.

CHELIUS ON AMPUTATION OF THE PORTIO VAGINALIS UTERI.—At the meeting of the Dresden Medical Society on December 4 (*Berliner Klinische Wochenschrift*, August 28), Dr. Chelius described the mode of operation adopted by himself. The patient is placed on her back, and for fixing the uterus he strongly recommends an instrument consisting of four hooks, each two of which are perpendicular to the other two. The *écraseur* is then used, and the neck is divided slowly (four or five hours). By this method the bleeding and pain are very slight. If it be desired to sew the wound together, it should not be attempted until the bleeding has ceased. Five or six days afterwards there is some hæmorrhage, which at times is by no means inconsiderable; it proceeds from within the uterus. Drs. Grenser and Winckel agreed with the speaker that this bleeding came from the internal surface of the uterus, and should not be mistaken for the menstrual flow; for no ovulation took place, as had been previously shown.

OSTERLOH ON TINCTURE OF EUCALYPTUS GLOBULUS IN PUERPERAL AFFECTIONS.—At a meeting of the Dresden Medical Society (*Berliner Klinische Wochenschrift*, July 28) Dr. Osterloh reported that he had given tincture of eucalyptus in thirty-one cases. The preparation was obtained from off a tree in the Botanical Gardens in Dresden. Where there was febrile disturbance without any apparent anatomical cause the drug acted beneficially, but in cases of primary acute inflammatory fever the results were nil. In the course of the debate, it was stated that the preparations sold by the druggists varied considerably in their effects.

W. C. GRIGG, M.D.

OPHTHALMOLOGY AND OTOLOGY.

CARRY ON A REMARKABLE CASE OF HERPES OPHTHALMICUS.—The *Lyon Médical* (no. 14) contains an account by M. A. Carry of a very interesting and remarkable instance of this rare disease; the attack recurred no less than eleven times while the patient was under his observation.

Françoise C., a silk-winder, aged sixteen, was admitted into the hospital November 6, 1873, on account of chronic rheumatism in several of her joints, which was in all probability due to her having been obliged from very early years to assist her mother, who was a laundress. She was anæmic, and had much pain in the joints of her lower limbs, and especially in the left hip-joint. There were some remains of ecthyma upon the lower extremities, but otherwise there were no signs of any eruptions on any part of her body. A week after admission, during the night, she was seized with intense intra-orbital pain on the left side; as morning came the pain subsided, but the eyelids were red and swollen, and were studded with a vesicular eruption which extended to the cheek; here and there the vesicles had coalesced, so as to form bullæ. The eyelids were separated with difficulty, but the conjunctiva had escaped, and there was but slight photophobia. The pain was much increased by pressure upon the supra-orbital and infra-orbital nerves, but there was no fever, and no loss of appetite. In three days, though the pain remained, the eruption had disap-

peared, and in a week from this she had a fresh attack of pain, followed by a similar eruption upon the right side. This was the only occasion on which the right side of the face was affected, but there was a speedy recurrence of the disease on the left side, with pain in the shoulder and axilla, and pain and tenderness along the course of the nerves of the brachial plexus. Each attack was ushered in at night with the same sudden pain, which was followed by the appearance of the eruption. Valerianate of quinine was given internally, and the eruption was dusted with starch-powder. With the third recurrence on the left side, the conjunctiva became implicated, and there was marked photophobia, and the root of the nose at the same time became covered with vesicles. The same treatment was adhered to after each attack, and the girl left the hospital at the end of December quite well apparently, with no marks of any eruption, and without pain, for by this time the pains in her hip-joint and lower limbs had entirely left her.

Three weeks after leaving the hospital, she appeared again after another attack; and on March 14, 1874, she presented herself, the pain and the eruption having recurred no less than six times since leaving the hospital. Her general health was now much impaired, she had a constant cough, and was feeble and out of health; menstruation had not appeared; there was some failure of memory, but no evidence of any lesion of any of the nervous centres. Up to this date the attack had recurred ten times, once on the right side and nine times on the left, the side originally affected.

There can be no doubt of the nature of the case above related, or that it could be other than a case of true herpes ophthalmicus. According to common experience such cases are rare; thus amongst 5,000 patients, Dr. Cohn could record but a single instance, and of 2,854 patients seen by Steffan, one only was the subject of this form of shingles. Dr. A. Hybord has collected ninety-nine cases on record; and if any further proof be wanted, it is supplied by the experience of Hebra, who observed but a single case amongst 102 cases of herpes spread over a period of nine years.

The case here recorded by M. Carry is remarkable in two ways, both as to the seat of the eruption, and the periodicity of its appearance. There is but one other case on record, mentioned by Mr. Jonathan Hutchinson, in which the eruption was limited to the eyelids, without invading the frontal region, and in this instance it is evident that a distinct region supplied by each of the two upper divisions of the fifth pair was attacked. The case also bears out an observation by Mr. Hutchinson, to the effect that the coats of the eyeball are only affected when the nasal branches of the nerve are implicated.

With regard to the recurrence of the attack, the case is unique, inasmuch as instances of periodical recurrences of shingles are till now unknown. It is a curious point in the case that the vesicles did not leave the scars in the integument, which are so characteristic of eruptions of this description. It is so rarely that one meets with bilateral shingles, that the symmetrical occurrence of the eruption on each side of the face is worthy of note. There is but one other case of this occurrence on record, also published by M. Hybord. If the researches of Charcot, of Cotard, of Weidner, and of Wagner, be well grounded, and the eruption in cases such as this be the cutaneous expression of a neuritis due to hyperæmia of the

spinal cord or to some ganglion analogous to it, such as the Gasserian ganglion, then M. Carry thinks we may assume that his patient was the subject of a hyperæmic condition of both ganglia, which was permanent in the left but only temporary on the right side, and he suggests that the cause in this instance was of a rheumatic character.

In support of his view that there probably was some affection of the ganglia, M. Carry quotes the report of the *post mortem* appearances which have been met with in two instances in patients who have died during an attack of shingles. One of these cases has been minutely reported and at length, by Oskar Wyss (*Archiv der Heilkunde*, 1871), and a third case is mentioned in which M. Carry was able to verify the conditions observed and described in the necropsy of the other cases. In M. Carry's case, the morbid appearances were a softening of the left half of the pons Varolii and of the fifth nerve on this side, congestion of the pia mater, which surrounded the three divisions of the nerve on this side, and a softening of the ganglion itself. It is unfortunate, however, that no more minute or microscopical examination was made. After the publication of this paper, M. Carry's patient was readmitted into the hospital on account of aggravated attacks of a hysterical nature, and of further returns of the herpes, so that the girl had suffered in all from thirteen attacks affecting the left side of the face, and of two only affecting the right side.

BOWATER J. VERNON.

COHN ON HEMIOPIA.—Dr. Hermann Cohn, of Breslau, relates five cases of hemiopia in Zehender's *Klinische Monatsblätter für Augenheilkunde* for June and July. From his perimetric observations of hemiops he shows—(1) that the dividing line between the percipient and non-percipient portions of the retina never passes through the blind spot; (2) that the dividing line is never a truly perpendicular line, but forms an indented line, which passes beyond a perpendicular drawn through the fixation point; and (3) that in all cases more or less peripheral defects exist in the percipient half. He relates a case of right-sided hemiopia after a wound which completely recovered, being the second case of recovery from hemiopia on record, the other being a case of Von Graefe's, recorded in Zehender's *Monatsblätter* for 1865. He tries to reconcile the perimetric observations with the descriptions of the decussation of the fibres at the optic commissure by Müller, Mandelstamm, Biesiadecki, and Michel, but finds he cannot explain all the varied defects by any of them.

W. LAIDLAW PURVES.

CORRESPONDENCE.

SODA-WATER.

(To the Editor of the LONDON MEDICAL RECORD.)

SIR,—Our attention has been drawn to an editorial note which appeared in your journal a short time since, embodying and remarking on Dr. Lankester's report on soda-water sold in his district. As Dr. Lankester's district is our district also, we feel that our reputation is by reference jeopardised when he says:

'From an examination of six specimens of this water, bought of chemists and druggists and publicans, none of them contained in a bottle a residue of 10 grains.'

As we guarantee to the profession continually that our alkaline waters are of the definite strength ordered by the Pharmacopœia, we must ask you, in fairness, to insert this

letter in the MEDICAL RECORD, to assure your readers that each bottle of our soda-water does contain, and always has contained, 15 grains of bicarbonate of soda. Our solution is always made of the strength of 30 grains in a pint; and, to be perfectly certain on the point, we have submitted a bottle of the water to volumetric analysis, and the result is evidence of 15.250 grains. We may add that each bottle is supposed to contain half-a-pint; but it may be 4 to 8 drachms more or less.

We are, etc.,

BLAKE, SANDFORD & BLAKE.

47 Piccadilly, Sep. 16, 1874.

MISCELLANY.

THE Berlin African Exploration Society is fitting out a second expedition to the interior of Africa. Herr Alexander von Hormayer, the well-known ornithologist, will be the leader of the expedition, and will go from St. Paul de Loanda by way of Kassimbe to Moatta Jambe.

THE Government of India, says the *Bombay Gazette*, has determined to perpetuate the memory of Dr. Stoliczka, the distinguished naturalist, who met his death on the return journey from Yarkand, by erecting, at the public expense, a tomb over his remains at Leh, and a tablet in the new Indian Museum at Calcutta.

A LARGE APPETITE.—A woman suffering from bulimia has lately died in Paris at the age of forty-three. She ate every day on an average about six pounds and a half of bread, and half a pound of meat. Bread formed her principal sustenance, of which she required about nine pounds to completely satisfy her appetite. The unfortunate creature earned about two shillings a day as a needle-woman, which, with a little income she possessed, was nearly all absorbed in providing food for her insatiable appetite.

CANNIBALS' TASTES.—In the anthropological section of the recent congress at Lille, reported in the *Revue Scientifique* of Sep. 12, one of the subjects discussed at some length was the practice of anthropophagy. M. Broca thereupon made some remarks on the different nature of the flesh of different races. He said that the cannibals, perhaps fortunately for us, do not like the flesh of whites; they find it bitter and salt, whilst, notwithstanding the latter quality, it does not keep well. Their special dainty is the flesh of the negro, of which they like the flavour, and which becomes dry by keeping rather than decomposes by the natural process.

WHERE WILL IT END?—The *République du Midi* asserts that there is at the present time in the Hôtel Dieu, at Montpellier, a rival patient to the fork swallower, who has so long occupied the attention of the French paragraph writers. The fresh object of interest has distinguished himself, in a moment of delirium, by swallowing a thermometer. It is by no means unusual for the students in French hospitals to lay down the thermometers which they have been using to obtain the temperatures of their patients on their beds, and it appears that a man, whilst in a state of high fever, managed to swallow an instrument which had been placed on his bed and forgotten.

MEDICINE AS A PROFESSION FOR WOMEN.—During the last week in August a congress of Danish physicians, more than 200 in number, met at Aarhus, when among other points under discussion, the claims of women to enter the profession were brought forward. The Congress came to no definite determination on the subject, but it listened with patience to the members who pleaded the cause of female students, and the general feeling at the meeting seemed to be that there was nothing to prevent women from treating the diseases of their sex with ability and success, while in the matter of obstetric practice it was in the highest degree desirable to transfer it completely from the hands of common midwives to those of women duly certificated by the University.

THE publishing house of Leuckart, in Breslau, has prepared for gratuitous distribution at the forty-seventh meeting of the Association of German Naturalists and Physicians, a catalogue of the principal works in medicine, pharmacy, and natural science which have appeared in Germany, with two illustrated appendices: viz., 1. The baths, mineral waters, and health resorts of Germany, Austria, and Switzerland; their temperature, analysis, etc. 2. A catalogue of surgical, orthopedic, and gynaecological instruments. The book contains 800 pages, and is dedicated by permission to the Managing Council of the Association.

DR. J. M. LEUPOLDT, ordinary Professor of Pathology, General Therapeutics, Psychology, and History of Medicine, in the University of Erlangen, died on August 21, at the age of eighty. Dr. Leupoldt had been actively engaged in lecturing since his appointment, nearly fifty years ago, to the chair of Medicine, the duties of which he continued to fulfil to within a short period of his death. Beyond the sphere of his own academical activity, he was best known by his comprehensive work on the *History of Medicine*, published in 1863. Among his fellow-townsmen Dr. Leupoldt was respected for the indefatigable energy with which he continued to the last to employ his talents and exert his influence to ameliorate the condition of the poor, and to promote objects of philanthropy.

BRAIN OF THE TERTIARY MAMMALS.—Professor Marsh has communicated to the Connecticut Academy of Arts and Sciences the result of his researches on the size of the brain of the tertiary mammals. He finds that the Eocene mammals had small brains, in some cases scarcely larger than those of the higher reptiles. In Dinoceras, little less than the elephant in bulk, the brain cavity is not more than one-eighth of the average size of existing rhinoceroses. In Tinoceras the smallness is quite as remarkable. In the gigantic Brontothoridæ of the American Miocene, the brain-cavity is very much larger than in the Eocene Dinoceras, being about the size of that of the Indian rhinoceros. In the Pliocene strata of the West a species of mastodon is the largest mammal, and although but little larger than Brontothorium it had a much bigger brain, though not equal to that of existing Proboscidiæ. He found a similar progressive development in the equine mammals from the Eocene to the Pliocene periods.

EFFECTS OF IMAGINATION.—At a late meeting of the Paris Académie des Sciences a letter was read from M. Volpicelli, of Rome, to M. Chevreul, in which the writer related that a Roman physician had asserted to him that, if a magnet were brought near to a nervous patient, magnetism had the effect of disturbing him in various ways, and notably in his condition of health. M. Volpicelli goes on to state that, being invited to experiment on a nervous subject at the San Spirito hospital, he practised a little ruse, and instead of taking with him a magnet, provided himself with a piece of unmagnetised iron. The patient scarcely saw the piece of iron before he fell into convulsions; his imagination became so highly excited that nervous disturbances of the most extreme character supervened. M. Volpicelli then made a second experiment. A magnet was placed in the hands of another person suffering from nervous disorder, who, when a few minutes had elapsed, was so extremely excited that it was necessary to take the magnet from him. M. Volpicelli, however, was convinced that the nervous disturbance was brought on by the sight of the magnet and not by magnetic action, and he was subsequently able to assure himself of the fact. The same person had to preside over a scientific meeting, and M. Volpicelli contrived to surround him with very powerful magnets, which were introduced into his chair, into the drawer of the table before him, and even under his feet, without his having the slightest suspicion of the trap laid for him. During the meeting, which lasted more than two hours, his nerves were not in the least affected; and when the meeting was over he declared, in answer to a question

put to him by M. Volpicelli, that he was perfectly well; but when it came to his knowledge that he had been surrounded by powerful magnets he was extremely surprised and alarmed, and began to have an idea that he could not have been so well as he thought.

THE PHYLLOXERA.—The subject which seems to cause the most interest in France at the present moment, and very naturally so, when the damage it inflicts upon the vines is considered, is that devastating little insect, the phylloxera. M. Lichtenstein, a well-known member of the Entomological Society of France, has just published some interesting details on this mysterious pest. He informs us that six years of arduous labour are finally crowned with success, and that he now thoroughly knows the habits of the phylloxera. He asserts that he has discovered its origin, and likewise a means of destroying it at small expense. At the present time, he tells us that it swarms on everything, like bees or ants. Winged insects come out of the earth in unheard of quantities; at a rough calculation about 500,000 from every two acres daily, and make their way towards the woods. There they lay their eggs on the cochineal oak (*Quercus coccifera*), the eggs being of two sizes, large and small. From these eggs issue small apterous insects, male and female, which couple immediately. M. Lichtenstein has not yet discovered how the product of this union, which is beyond any doubt the source of the next year's colonies, returns to the vineyard; but he is continuing his endeavours to ascertain this point. It is, however, he asserts, easy to burn and destroy millions of these insects by setting fire to the clumps of the oaks mentioned, which surround the vineyards. This heroic remedy should, he says, be applied at once, since the insect is only thus within reach once a year. The epochs when this occurs vary according to the weather and other circumstances; thus, whilst in one locality the eggs are already opening, in another they are scarcely laid, and in yet another the laying is going on as fast as possible. M. Lichtenstein here notes that though he terms the substance deposited by the insects on the oak an 'egg,' it would be more accurate to term it 'chrysalis,' since it gives origin to a perfect insect, and not to a larva. Truly Protean in its nature, the Phylloxera vastatrix presents such extraordinary metamorphoses that it upsets all the received data of entomological science. It begins as an egg, finishes by another egg, and altogether passes through a too complicated kind and number of changes to be described without considerable space and detail.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17s. 4d.; free by post, 19s. 6d.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & CO., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The First Volume, containing upwards of Two Thousand Articles abstracted and compiled by a staff of Fifty Hospital Surgeons and Physicians, is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for the year 1873 are also ready, price 1s. 6d. each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & CO.—Calcutta: THACKER, SPINK & CO.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & CO.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & CO., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, SEPTEMBER 30, 1874.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

ADVICE TO ENGLISH MEDICAL STUDENTS VISITING PARIS.

Many English students, after they have passed their examinations, visit Paris during the winter session, but do not exactly know, at first, how best to employ their time. The following synopsis of medical studies in Paris will, we hope, help them in some degree.

To attend the hospitals in Paris, permission must be got from the Assistance Publique, No. 3, Avenue Victoria, where, on asking for 'une carte pour visiter les hôpitaux de Paris,' and at the same time showing one's diploma or other evidence of being in the medical profession, a ticket will at once be given without any payment. This ticket has to be shown to the porter of the hospital, if asked for. Students without one are sometimes refused admission. The hospital visit is always early in the morning, from 8.30 to 11 A.M.

It will generally be found that the hospitals in the *Quartier Latin*—the students' quarter, viz., the Hôtel Dieu, La Charité, L'Hôpital des Cliniques, La Pitié, are so crowded that there is no getting near the patients; but on the other hand, these hospitals have the advantage of a clinical lecture after the visit, which the more distant hospitals, as Beaujon, Saint-Antoine, Necker, Lariboisière, have not. All the hospitals above named are general hospitals, and take in surgical and medical cases, and some of them midwifery. In the St. Louis, there is a special department for diseases of the skin; and, during the summer, Dr. Hardy gives a weekly clinical lecture on these diseases. There is a very good but small museum, containing specimens of skin-diseases, attached to this department. Dr. Péan, who is the most successful operator in Paris for ovariectomy cases, has surgical wards in the same hospital, and is one of the best men for a student to attend, as he thoroughly explains how and why he does every operation. The Hôpital des Enfants, in the Rue de Sèvres, next door to the Hôpital Necker, receives only children under fifteen years of age. Dr. Roger, one of the most eminent authorities on children's diseases, gives a clinical medical lecture every Monday at 9 A.M.

The hospitals specially appropriated to syphilitic patients are—L'Hôpital du Midi for men, and Lourcine for women. A special permission to visit these two hospitals must be got from the Assistance Publique. The visit is at the same hour as at the other hospitals, viz., about 9 A.M. Students specially interested in the treatment of the insane will visit Ste. Anne and La Salpêtrière.

The Lectures of the Faculty take place in the Rue

de l'École de Médecine, and nearly all in the afternoon. They are all public. The most worth attending during the winter session are those given by Dr. Dolbeau, on 'Surgical Diseases of particular Regions of the Body' (maladies chirurgicales des régions). As a rule, the lecturers of the Faculty treat of limited subjects, and it would require seven or eight years' attendance to get through a complete course of (for instance) anatomy. It is not so with the lectures at Clamart (17 Rue du Fer à Moulin, Avenue des Gobelins). Here the lectures are concise and practical, and are as follows:—Surgical Anatomy, by Dr. Tillaux, at 4 P.M., Tuesdays and Fridays; Physiology, by Dr. Terrillon, at 4 P.M., Wednesdays and Saturdays; Histology, by Dr. Grancher, at 2 P.M., Tuesdays and Fridays. All these lectures are public. The student who wishes to take up Histology can do so by entering his name as 'un étudiant des hautes études,' at the Collège de France, in the Rue des Écoles. The instruction here is also gratis. M. Ranvier, one of the most eminent histologists in the world, has the superintendence of the laboratory.

Dr. Galezowski gives every day at 12 A.M., at 26 Rue Dauphine, a free clinical lecture on Diseases of the Eye. Students here can practise with the ophthalmoscope, and learn much in a short time.

Students who wish to dissect will either have to go to the École Pratique, in the Rue de l'École de Médecine, or to Clamart. Operations, as a rule, are not allowed during the winter session; but may be done during the summer, when dissecting is impossible. At the École Pratique, foreign doctors can dissect through the entire winter session for sixty francs; but they will get, at most, two parts during the session. Clamart has much better dissecting rooms as regards hygienic arrangements, etc. Here foreigners can dissect by becoming pupils of the prosectors. Very good demonstrations are also given by senior students, internes des hôpitaux, at charges varying from 30 to 50 francs the course. The dissecting rooms at Clamart are open from 12 to 4 P.M.

It will thus be seen from the above that the hospital work must be done in the morning, leaving the afternoon free for lectures or dissecting.

The following courses of lectures will be delivered in the Paris Faculty of Medicine during the winter session, commencing Monday, November 3.

Medical Physics.—Professor Gavarret: General Physics—Heat, Electricity, Light, Wed. and Fri., 12. Biological Physics: Physiological Phenomena of Voice and Hearing, Mon., 5.

Medical Pathology.—M. Fernet, agrégé, for Professor Axenfeld, Mon., Wed., Fri., 3.

Anatomy.—Professor Sappey: the Respiratory, Urinary, and Generative Apparatus, Mon., Wed., Fri., 4.

General Pathology and Therapeutics.—Professor Chauffard: Disease in General, Pathological Classifications, General Etiological and Microscopic Characters of the Different Classes of Diseases, Mon., Wed., and Fri., 5.

Medical Chemistry.—Professor Wurtz: General Chemistry, Thurs. and Sat., 12; Biological Chemistry (Chemical Study of Digestion), Tues., 4.

Surgical Pathology.—Professor Dolbeau: Surgical Diseases of Regions, Tues., Thurs., and Sat., 3.

Surgical Operations and Apparatus.—Professor Léon le Fort: Treatment of Diseases of the Bones, Joints, and Vessels, Tues., Thurs., and Sat., 4.

Histology.—Professor Robin : Generation and Development of the Anatomical Elements, and of the Humours, Tues., Thurs., and Sat., 5.

History of Medicine and Surgery.—Professor Lorain : The Pulse, Historical Studies, Some Epidemic and Contagious Diseases, History, Tues., Thurs., and Sat., 5.

Clinical Medicine.—M. Hayem for Professor Bouillaud, and Professor G. Sée, at La Charité. Professor Béhier, at the Hôtel-Dieu. Professor Lasègue, at La Pitié. All from 8 to 10 A.M. daily.

Clinical Surgery.—Professor Richet, at the Hôtel-Dieu. Professor Gosselin, at La Charité. Professor Verneuil, at La Pitié. Professor Broca, at the Clinical Hospital. All from 8 to 10 A.M. daily.

Clinical Midwifery.—Professor Depaul, at the Clinical Hospital of the Faculty, 8 to 10 A.M. daily.

Diseases of Children.—Professor H. Roger, at the Children's Hospital, Mon., Thurs., and Sat., 8.30 A.M.

THE GERMAN MEDICAL SCHOOLS.

We give this week, for the information of students who may be intending to pass the winter at one of the German medical schools—including that of Vienna—statements of the subjects taught and of the teachers in some of the principal universities. Among these, the first rank has for some time been held by Berlin and Vienna ; but other of the universities, notably Würzburg and Leipzig, have in recent years grown considerably in favour. A few notes on the principal attractions presented by the several institutions may be acceptable.

In Berlin, the great inducement to students to visit the university is the teaching of pathology. The Pathological Institute, which owes its existence in its present form to Professor Virchow, and has been under his direction for eighteen years, has served as the prototype of other institutions of the kind in Germany and elsewhere. It has sent out a host of disciples, who have carried far and wide the influence of its celebrated teacher ; and among those who have been his assistants in teaching are to be found the names of many who have made for themselves reputations in science—such as Hoppe-Seyler, Von Recklinghausen, Hüter, Cohnheim, Liebreich, Ponfick, etc.

The institute, situated within the grounds of the Charité, contains a lecture-theatre, a room for demonstrations, a museum, a chemical laboratory, a histological laboratory, a suite of rooms for the *post mortem* examinations, private rooms for the professor and his assistants ; while in the basement floor there are kept the collection of guinea-pigs, rabbits, white rats, etc., the usual signs of experimental activity. The chemical laboratory has recently had an additional wing built to it, to furnish accommodation for physiological and other apparatus.

Three times in the week Professor Virchow gives demonstrations of pathological anatomy, nominally at eight o'clock, but actually from half an hour to an hour and a half later. These last from two to three hours, and the demonstration has sometimes been known to terminate nearer one o'clock than ten. One out of three days in the week—Monday—is devoted to demonstration over the *post mortem* table, and this is an occasion that the student should endeavour not to miss. One or two students are asked to volunteer to do the work, under Virchow's direction ; and although this system is more to the advan-

tage of the few than of the many, and often proves rather tedious to the spectators, students may be counselled to be none the less assiduous in their attendance. When the session is considerably advanced, Virchow relegates this work to his senior assistant, who carries it out with the same care and elaborateness. The ordinary *post mortem* examinations are made throughout the forenoon, and are chiefly attended by those who have followed the clinical history of the cases. The material from them is reserved for demonstration by the professor on the mornings of Wednesday and Saturday. The demonstrations take place in a large room with tables specially arranged for the purpose, the specimens being placed on wooden trays and circulated among the students. The professor usually commences with an important specimen or group of organs from one case, on which he expatiates for a considerable time, the remaining specimens being despatched in quick succession. It is much to be regretted that many of the students are unable to see the specimens until after the demonstration is over. Plans have been tried to put all the students on an equal footing in this respect, but the chief grievance, viz. the congregating of a number of heads over a tray, and the *têtes-à-tête*, and consequent delays that result, have perhaps no other remedy than in the disinterestedness of the students themselves.

On the three remaining days of the week not devoted to demonstration, a course of pathological histology is given by one of the assistants, under Virchow's direction. It has been found that many students come to the Pathological Institute imperfectly grounded in normal histology, and on this account, courses of instruction in the microscope are given.

In addition to his demonstrations, Professor Virchow lectures on four days of the week at 1 P.M. on general pathology.

Every encouragement is given to students who are desirous of working out, in the laboratory of the institute, any special point in pathology. A library of books of reference is available, and a place in the laboratory will, if possible, be assigned to the student, free of charge. It will be found more convenient for the student to have his own microscope. The chemical laboratory is also open to students for researches or for exercises in physiological and pathological chemistry, under the direction of Professor Salkowski ; a fixed charge per session (3*l.* or 4*l.*) being made, to cover the cost of material.

Of clinical teachers, Berlin possesses some of the most eminent—men whose names are too well known to require more than mention. In Medicine, there are Frerichs and Traube ; in Surgery, Langenbeck and Bardeleben ; in Aural Surgery, Lucae ; in Psychology, Westphal, etc. We must refer to the reader to page 612 for the names of the professors and teachers of the various branches of medical science in the university.

Like Berlin, Vienna has a school of pathology, under the guidance of an eminent teacher—the veteran Rokitsansky ; who still retains his professorship, though a few months ago negotiations were carried on with von Recklinghausen, Cohnheim, and other eminent pathologists of the modern school, in the anticipation of his retirement. Celebrated, however, as the pathological school of Vienna has been, and instructive as its teaching still is, the material is

not utilised with the same elaborate care as at Berlin under the management of Virchow. Still there are great opportunities for the study of pathological anatomy; and the course of Experimental Pathology, under Professor Stricker, is highly instructive.

It is the number and variety of special courses that form perhaps the great attraction of the Vienna school; and in these it has the pre-eminence over Berlin. These special courses are tutorial, of limited duration (four to eight weeks), and are attended by numbers varying from half-a-dozen to forty or more. The courses for Diseases of the Throat and Ear are much attended; and the clinical teaching of Professor Hebra on Diseases of the Skin is greatly frequented by foreign students. Among other teachers in this department whose lectures should be attended, are to be mentioned Drs. Neumann and Kaposi.

We give also the prospectuses of the winter courses at the Universities of Breslau, Göttingen, Leipzig, Munich, and Würzburg. Breslau, which has lately been the place of meeting of the Congress of German Naturalists and Physicians, possesses among its university staff several eminent contributors to medical science. Among them may be specially mentioned Heidenhain in Physiology, Cohnheim in Pathology, Voltolini in the Surgery of the Throat and Ear, and Spiegelberg in Midwifery. In Leipzig there are the well known names of His (in Anatomy), Reclam (in Hygiene), Thiersch (in Surgery), Coccius (in Ophthalmology), Wunderlich (in Medicine), Credé (in Midwifery), Leuckart and Carus (in Comparative Anatomy). Munich reckons among its teachers Voit (in Physiology), Buhl (in Pathology), Nussbaum (in Surgery), Pettenkofer (in Hygiene), Ziemssen (in Medicine), etc. The University of Würzburg has already been spoken of in the LONDON MEDICAL RECORD (December 24, 1873) as growing in favour with English students; its chief attractions are the teachings of Kölliker (in Anatomy), Gerhardt (in Medicine), and Scanzoni (in Midwifery).

THE MEDICAL SCHOOL IN VIENNA.

The Vienna Medical School is noted for its large hospital (the Allgemeine Krankenhaus) and for the extent to which the teaching of special departments is carried on, as well as for the eminence of the teachers.

The General Hospital, in the Alsergrund, founded by the Emperor Joseph II., in 1784, is capable of accommodating about 3,000 patients. There are 99 wards, 55 for males, 44 for females; there are also some small wards capable of containing six or eight patients. The hospital is divided into seven medical, four surgical, and six special departments, the latter being for diseases of the skin, eye, chest, and nervous system, diseases of women, and syphilis. There are two medical clinics, under Professors Duchek and Von Bamberger, two surgical clinics under Professors Von Dumreicher and Billroth, clinics for Diseases of the Eye under Professors Von Arlt and Stellwag von Carion, and clinics for Obstetrics and Diseases of Women under the charge of Professors Carl Braun-Fernwald, Späth, and Gustav Braun, one being for midwives. Clinical instruction is given in Diseases of the Skin by Professor Hebra; in Syphilis, by Professor Sigmund (Von Ilanor); in Laryngoscopy, by Dr. Schrötter; in Diseases of

Children, by Professor Widerhofer; in Psychology, by Professor Meynert; and in Otology, by Professor Gruber. A considerable portion of the school is also situated within the hospital; thus there are the Pathological Museum and *post-mortem* room, under the direction of Professor Baron Rokitsansky; the room for medico-legal necropsies, under Professor Dlauhy; the Institute for Experimental Pathology, under the direction of Professor Stricker; and the Institute of Chemical Pathology, under Professor Ludwig. The Anatomical Museum and Dissecting Room, the Anatomical Institute and Dissecting Room, under the direction of Professor Langer; the Physiological Institute, where Practical Physiology is carried on under Professor Brücke; the *Materia Medica* Museum, and the Medical Library, are outside the hospital, in the Alsergrund.

The courses of lectures and practical instruction in the medical faculty of the University are numerous, and are divided among the professors, their assistants, and the private teachers (*privat-docenten*). The special courses of instruction are those which are especially attractive to the foreign student. Their duration is usually from four to eight weeks, a new course generally commencing a few days after the former one is finished. The fees are greater than for the ordinary classes, usually varying from fifteen to twenty florins. The instruction given in them is demonstrative and practical.

In the department of *Anatomy*, the teachers are Professors Voigt and Langer (Human Anatomy); Professor Wedl (Normal and Pathological Histology); Professor Meynert (Nervous System); Professor Baron Rokitsansky and Professor Klob (Pathological Anatomy); Dr. Toldt (Use of the Microscope and Practical Histology); Dr. von Patruban (Surgical Anatomy); Dr. Friedlowsky; and Dr. Kundrat, assistant to Professor Rokitsansky.

The professor of *General Physiology* is Dr. Brücke; and the other teachers in the department are Professor Schwanda (Medical Physics); Dr. Schenk (Embryology); Dr. Exner (Microscopic Exercises and Physiological Optics).

In the department of *Materia Medica and Therapeutics*, the teachers are Professor Schroff (Pharmacology and Toxicology); Professors Benedikt and Schwanda and Dr. Schultz (Electrotherapeutics); Chronic Nervous Diseases and Electrotherapeutics (Dr. F. Fieber); Dr. Winternich (Hydrotherapeutics); Professor Seegen (Balneology).

In the department of *Medicine*, Special Medical Pathology, Therapeutics, and Clinical Medicine, are taught by Professors Duchek, Von Bamberger, and Löbel. General Pathology is taught by Professor Stricker; and the Experimental Physiology and Pathology of the Central Nervous System by Dr. Obersteiner. Instruction in Percussion and Auscultation is given by Professors Duchek and Bamberger and their assistants, and by Drs. Kolisko and Schrötter; and the students are trained in the Examination of Patients and the Diagnosis and Treatment of Disease, by Professors Seligmann, Stern, and Schwanda, and Drs. Rollet and Schnitzler. Laryngoscopy and Rhinoscopy are taught by Dr. Schrötter, Dr. Störk, and Dr. Schnitzler. Instruction regarding Diseases of the Abdomen is given by Dr. von Györy; and regarding Diseases of the Nervous System by Professor Benedikt, Dr. Rosenthal, and Dr. Oser. Dr. Winternitz gives instruction in the Application of Hydrotherapeutics to the Treatment of Internal

Diseases. Professor Drasche lectures on Epidemiology.

In the department of *Surgery*, instruction in Clinical Surgery, with Lectures on Surgical Pathology and Therapeutics, are given by Professors Baron von Dumreicher, Billroth, and Dittel. Practical Surgery is taught by Professors Dumreicher and Billroth and their assistants, and by Professors Cessner, Weinlechner, and Böhn, and Drs. Salzer, Von Mosetig, Neudörfer, Hofmök, Albert, and C. Fieber. Dr. Neudörfer gives instruction in Resection of the Large Joints. Dr. Englisch and Dr. Ultzmann lecture on Diseases of the Urinary and Generative Organs. Fractures, Dislocations, and Orthopædic Surgery, with Instruction in the Application of Bandages, etc., are under the charge of Drs. Englisch and Hofmök; Aural Surgery is taught by Professors Gruber and Politzer, and Dr. Urbantschitsch; and Dental Surgery by Drs. Zsigmondy, Steinberger, and Scheff.

Ophthalmology and the Use of the Ophthalmoscope are taught by Professors von Arltz, Stellwag von Carion, and by Drs. von Reuss, Kämpf, Schnäbel, Hock, and Bergmeister.

Midwifery, theoretical and practical, is taught by Professors Braun von Fernwald, Späth, and Gustav Braun, and their assistants, and by Dr. Mayrhofer and Dr. Carl Rokitsansky. Dr. Gustav Braun and Dr. Habit deliver lectures on Obstetrics to Midwives. Instruction regarding Diseases of Women and Operations is given by Drs. Böhm, Salzer, Funk, Chrobak, C. Rokitsansky, and Lott. Diseases of Children are taught by Professors Widerhofer and Weinlechner, and by Drs. M. Pollitzer, Schuller, Fridinger, Fürth, Monte, and Fleischmann.

Clinical Instruction, and Lectures on *Diseases of the Skin* are given by Professor Hebra, and by Drs. Reder, Wertheim, Neumann, Auspitz and Kaposi; and in *Syphilis* by Professors Sigmund, Zeissl, Auspitz, Kohn, and Kaposi.

Psychological Medicine is taught by Professors Meynert, Schlager, and Leidesdorf; and *Forensic Medicine* by Professor J. Dlauhy. Instruction in Hygiene is given by Professor Seegen; and in Military Hygiene by Professor Baron von Mundy.

UNIVERSITY OF BERLIN.

The following courses of tuition will be given during the winter session, commencing October 16, and ending March 9, 1875.

History of Medicine.—Professor Hirsch, General History of Medicine, Mon., Tues., Thurs. 4. Dr. Falk, History of Medicine to the beginning of the nineteenth century, three times weekly. Dr. Hirschberg, the Mathematical Foundations of Medical Statistics, once weekly.

Anatomy.—Professor Reichert, Theoretical Histology, Mon. 10; Anatomy of the Brain and Spinal Cord, Sat. 12; Anatomy of the Human Body; Texture and Microscopic Structure of the Human Body; Anatomical Demonstrations, daily, 9 to 12 and 2 to 4. Professor Hartmann, Anatomy of the Organs of Sense, Fri. 3; Bones and Ligaments, Fri. and Sat. 9.

Physiology.—Professor Du Bois-Reymond, on certain Recent Discoveries in Natural Science, Mon. 6; Experimental Physiology, daily, except Mon. 10; Physiological Exercises in the Laboratory. Professor Munk: Generation in Man and Animals,

Tues. 5; General and Special Physiology of Nerves and Muscles, with experiments, four times weekly.

General Pathology and Therapeutics.—Professor Virchow, General Pathology and Therapeutics, with Pathological Anatomy, daily, except Sat. 1; Course of Demonstrations of Pathological Anatomy and Histology, with Instructions in making *post mortem* Examinations, Mon., Wed., Sat., 8 to 10; Practical Course of Pathological Histology, Tues., Thurs., Fri., 8 to 10. Professor Salkowski: Animal Ferments, once weekly; Physiological and Pathological Chemistry, three times weekly; Demonstrations in the Laboratory of the Pathological Institute, daily. Dr. von Lauer: General Medico-Chirurgical Semiotics, Mon. and Thurs., 3; Medico-Chirurgical Therapeutics, Tues. and Fri., 3.

Special Pathology and Treatment of Disease.—Professor Frerichs, three times weekly, 12. Professor Hirsch, daily except Sat., 5. Dr. Bergson, daily, 6. Dr. Riess, Miasmatic and Contagious Diseases, once a week. Professor Meyer: the Examination of Patients, with Conversations on special subjects in Pathology and Therapeutics, Sat., 1. Dr. Schiffer: on Fever and Inflammation, with Experimental Demonstrations, twice weekly; on the Physiology and Pathology of the Urine, once weekly. Professor Jacobson: Medical Physics, Wed. and Sat., 5; Diseases of the Lungs, with Demonstrations, twice weekly. Dr. Fränzel: Auscultation and Percussion, with practical Instruction, Mon., Wed., and Fri., 12; Course of Laryngoscopy. Professor Waldenburg: Practical Course of Percussion, Auscultation, etc., Tues., Fri., and Sat., 6; Practical Laryngoscopy, Wed., 6. Dr. Guttmann: Percussion, Auscultation, twice weekly; Diagnosis of Internal Diseases. Dr. Ewald: Selected Chapters in Special Pathology and Therapeutics, three times weekly; Percussion and Auscultation. Dr. Tobold: Laryngoscopy, with Practical Demonstrations, three times weekly. Dr. Fränkel: Antroscopy, or the Examination of Cavities of the Body by means of Sight; Courses of Laryngoscopy and Rhinoscopy. Dr. Bose: Laryngoscopy, with Demonstrations, once a week. Dr. Senator: General Semiology and Diagnosis, with Demonstrations and Practical Examinations, three times weekly; Diseases of Children, with Demonstrations, Sat., 11.

Diseases of the Nervous System.—Professor Westphal, once weekly. Dr. Hitzig: Lecture and Demonstration, twice weekly. Dr. Sander: Psychiatry, twice weekly, 6; Course of Diagnosis of Mental Diseases. Dr. Mendel: Civil and Criminal Responsibility, for medical and legal students, Wed., 3; Psychiatry with Demonstrations and Practical Exercises, Mon., Wed., and Sat., 6; Diseases of the Nervous System, including Mental Diseases, Mon., Wed., Thurs., and Sat., 5.

Materia Medica.—Professor Liebreich: Materia Medica with Experiments, Tues., Wed., Thurs., and Fri., 4; Anæsthetics with Experiments, Mon., 4; Practical Exercises in the Pharmacological Institute. Dr. Bergson: the Art of Prescribing, Mon. and Thurs., 5. Dr. Bernhardt: the Art of Prescribing, once weekly; Electro-Therapeutics, once weekly. Dr. Ewald: Dietetics, once weekly. Dr. Hitzig: Medical Electricity, Fri., 6.

Surgery.—Professor Jüngken: General and Special Surgery, Mon., Tues., Thurs., and Fri., 5; Hernia, Wed. and Sat., 5. Professor Bardeleben: Surgery, five days weekly, 11; on Wounds, Sat., 11. Dr. Ravoth: General and Special Surgery, six

times weekly. Dr. Mitscherlich : General and Special Surgery with Demonstrations, six times weekly, 10. Dr. Wolff : General and Special Surgery with Demonstrations, Mon., Wed., and Fri., 4; Bandaging, Wed. and Sat., 4. Diseases of the Urinary Passages, Bladder, and Rectum, with Demonstrations, Thurs., 4. Professor Gurlt : Fractures and Dislocations, Wed. and Sat., 4; Surgical Operations on the Dead Body, 9 to 11. Dr. Bosc : Fractures and Dislocations, three times weekly. Dr. Busch : Surgical Anatomy with Demonstrations, Mon., Thurs., and Sat., 8; Course of Bandaging. Dr. Güterbock : Gypsum and other Bandages, with Demonstrations, Sat., 6 to 7.30; Treatment of Wounds, Wed. 6. Professor von Langenbeck : Plastic Surgery, with Surgical and Anatomical Demonstrations, three times weekly, 12. Dr. Trendelenburg : Surgical Diseases of Children, Wed.; Diseases of Bones and Joints, Tues., Fri., and Sat. Dr. Pincus : Syphilitic Diseases, and Diseases of the Skin and Hair, Mon. and Thurs., 5. Dr. Burchardt : Syphilitic Diseases, twice weekly; Cutaneous Diseases, twice weekly. Dr. O. Simon : Syphilitic Diseases with Demonstrations, twice weekly; Skin Diseases, three times weekly.

Ophthalmology.—Professor Schweiger : the Theory of the Ophthalmoscope, Sat., 12; Ophthalmology, Tues. and Thurs., 12; Operations on the Eye, Wed. and Sat., 11. Dr. Hirschberg : Introduction to the Study of Modern Ophthalmology, three times weekly.

Otology.—Professor Lucae : Diseases of the Ear with Demonstrations. Dr. Weber-Liel : Demonstrations and Practical Course on Diseases of the Ear.

Odontology.—Professor Albrecht : Diseases of the Teeth and Mouth, Mon., Thurs., Sat. 6. Demonstrations, daily, 2.

Obstetrics and Gynaecology.—Professor Martin : Gynaecology and Midwifery, daily, 5. Dr. Schöller : Theoretical and Practical Midwifery, Mon., Tues., Thurs. and Fri. 4; Course of Operative Midwifery, with Exercises on the Phantom. Dr. Kristeller : Causes and Treatment of Sterility, Wed. 6; Exercises in the Newest Methods of Obstetric Examination and Operation. Dr. Cohnstein : Gynaecology, Wed. and Sat. 5; Midwifery, Mon., Wed. and Fri. 12; Courses of Operative Midwifery, with Exercises on the Phantom, Tues. and Thurs. 5; Dr. Fasbender : Gynaecology, Sat. 12; Obstetrics, Wed. and Fri. 4; Obstetric Operations with Exercises on the Phantom, Mon. and Thurs. 4. Dr. Mayer : Gynaecology, Wed. and Sat.; Tumours of the Female Sexual Organs, Wed.; Dr. Wernich : The Dietetic Management of Puerperal Women and Infants, Sat. 1; Obstetrics, Tues., Wed., Thurs., Fri.

Forensic Medicine, Hygiene, etc.—Professor Liman : Forensic Medicine for Medical Students, with Demonstrations, Mon. and Wed., 12.30. Professors Liman and Skrzeczka : Course of Medicolegal Examinations of the Dead Body and Forensic Practice, in the Anatomical Buildings of the Royal Forensic Institute, 1. Professor Liman : Forensic Medicine for Students of Law, with Demonstrations, Sat., 11 to 1. Professor Skrzeczka : Forensic Medicine for Students of Law, Tues., Thurs., and Fri., 6; Forensic Medicine for Medical Students, Mon., Wed., and Sat., 5; Select Subjects in Medical Police, twice weekly. Dr. Zülzer : Public Hygiene and Medical Statistics, with Practical Exercises,

Wed. and Sat., 2; Acute Infectious Diseases, Mon., 2. Dr. Burchardt : Hygiene, twice weekly. Dr. Ravoth : On the Care of the Sick and on Hospitals, Sat., 5. Dr. Falk : Violent Modes of Death, Tues., 6.

Clinical Instruction.—Professor Traube : Clinical Diagnosis, in the Charité Hospital, six times weekly 9 to 11. Professor Frerichs : Clinical Medicine, in the Charité Hospital, six times weekly, 11 to 12.30. Professor Meyer : Medical Polyclinic, five times weekly, 1. Dr. Henoch : Clinic of Diseases of Children in the Charité Hospital, Mon., Wed., Thurs., and Fri., 12; Polyclinic, daily, 1. Professor von Langenbeck : Clinical Surgery in the University Clinical Hospital, six times weekly, 2. Professor Bardeleben : Clinical Surgery in the Charité Hospital, six times weekly, 9 to 11. Professor Martin : Obstetric and Gynaecological Clinic and Polyclinic, in the Clinical Lying-in Hospital and in the Charité Hospital, daily, 9.30 to 11. Professor Schweigger : Diseases of the Eye, Mon., Wed., and Fri., 12. Professor Lucae : Diseases of the Ear (Polyclinic), Tues. and Fri., 9. Professor Westphal : Diseases of the Nerves and Mind, in the Charité Hospital, Mon., Wed., and Sat., 8.30 to 10. Dr. Lewin : Syphilis and Diseases of the Skin, in the Charité Hospital, Mon., Tues., Wed., Thurs., and Sat., 11.

UNIVERSITY OF BRESLAU.

The winter session at this university will commence on October 15.

History of Medicine, etc.—Professor Haeser : Medical Methodology, Thurs., 4; History of Medicine, Tues. and Fri., 4.

Anatomy.—Professor C. Hasse : Morphology of the Skeleton, once a week; Muscles and Viscera, daily, 11; Topographical Anatomy, four times weekly; Comparative Anatomy, three times weekly; Anatomical Demonstrations. Professor Grosser : Vessels, once weekly; Bones and Ligaments, Wed. and Sat., 11. Dr. Joseph : Syndesmology, once weekly; Osteology, twice weekly; Anthropology, three times a week.

Physiology.—Professor Heidenhain : Physiological Colloquies, Mon., 4; Experimental Physiology on the Organs of Sense and the Vegetative Functions, daily, 12; Practical Exercises in the Physiological Institute, daily in the forenoon. Professor Auerbach : the Principles and Methods of Microscopic Investigation, once weekly; Special Physiology of the Nervous System, twice a week. Dr. Gscheidlen : the Blood and Respiration, once weekly; on Physiological Method, twice a week; Exercises in Physiological Chemistry.

Pathology.—Professor Cohnheim : General Pathology, Tues., Thurs., Fri. and Sat., 2; Demonstrative Course of Pathological Anatomy, with Instruction in making Necropsies, Mon. and Wed., 1 to 3, Sat., 10 to 12; Experimental and Microscopical Exercises in the Pathological Institute, daily, in the forenoon.

Medicine.—Professor Biermer : Contagious Diseases, Fri. and Sat., 12; Pathology and Treatment of Diseases of the Respiratory Organs, Mon., Tues., Wed., Thurs., 12. Professor Grosser : Parasites of Man, once weekly. Dr. Ebstein : Diseases of the Organs of Digestion, once a week; Auscultation and Percussion, with Exercises, three times a week; Diagnosis of Internal Diseases, once a week. Dr. Berger : Diseases of the Nervous System, with De-

monstrations, twice weekly. Dr. Joseph : the Parasites of Man, twice a week.

Surgery.—Professor H. Fischer : General Surgery, daily, 8 ; Tumours, Sat., 8. Professor Klopsch : Diseases of the Urinary Organs, twice weekly. Dr. Paul : Practical Surgery, twice weekly. Dr. Richter : Resections, once weekly ; Selected Chapters of Forensic Surgery, three times weekly. Dr. Maas : Selected Chapters of Special Surgery, twice weekly ; Fractures and Dislocations, with Instruction in the Application of Splints and Bandages, three times weekly. Dr. Voltolini : Laryngoscopy and Rhinoscopy, Wed., 3. Dr. Sommerbrodt : Clinic Diseases of the Larynx and Pharynx, once weekly. Dr. Gottstein : Exercises in Rhinoscopy and Laryngoscopy, twice weekly.

Ophthalmology.—Professor Förster : Diseases of Refraction and Accommodation, Thurs., 12 ; Ophthalmology, with Demonstrations and Clinical Exercises, Mon., Tues., and Fri., 12. Professor H. Cohn : On Myopia, once weekly ; Course of Ophthalmoscopy, twice weekly ; Practical Ophthalmic Surgery, twice weekly. Dr. Magnus : Ophthalmoscopic Exercises on the Living and on Artificial Eyes, twice weekly ; Operations on the Eye, once a week.

Otology.—Professor Voltolini : Anatomy of the Organ of Hearing as far as regards its Diseases, Mon., 4. Dr. Gottstein : Treatment of Diseases of the Ear, once a week.

Dental Surgery.—Dr. Bruck : Anatomy, Physiology, and Development of the Teeth, once weekly ; Dental Surgery, four times a week.

Syphilis and Skin-Diseases.—Dr. Köbner : Exercises in the Diagnosis of Syphilitic Diseases, Sat., 11 to 1 ; Clinical Demonstrations of Diseases of the Skin and of the Acute Exanthemata, three times a week.

Obstetrics and Gynaecology.—Professor O. Spiegelberg : Diseases of the Ovary, Wed., 4 ; Midwifery, Mon., Tues., Thurs., and Fri., 4. Professor Freund : Gynaecological Operations, twice a week ; Diagnosis of Diseases of Women, with Exercises, six days weekly. Dr. Fränkel : Metrorrhagia in Pregnant, Parturient, and Puerperal Women, once weekly ; Obstetric Operations with Exercises on the Phantom, three times weekly. Dr. Landau : Diseases of Puerperal Women, once weekly ; Gynaecology, four times a week.

Materia Medica and Therapeutics.—Professor Haeser : Pharmacology, Mon., Tues., Thurs., Fri., and Sat., 5. Dr. Reymann : Selected Chapters of General Therapeutics. Dr. Lewald : Repetitions of Materia Medica, with Pharmacological Demonstrations, twice a week. Dr. Berger : Electrotherapeutics, once a week.

Forensic Medicine and Hygiene.—Professor Neumann : Forensic Psychology. Professor Friedberg : Public Health, with Demonstrations, Tues. and Fri., 4 ; On Responsibility, with Demonstrations, Wed. 4. Dr. Hirt : Diseases of Artisans, once weekly ; Public Health, once weekly ; Forensic Medicine, twice weekly.

Clinical Instruction.—Medicine : Professor Biermer, Clinic and Polyclinic, six days weekly, 10.30 to 12. Surgery : Professor Fischer, Clinic and Polyclinic, daily, 9.30 to 11. Diseases of the Ear, Larynx, etc. : Dr. Gottstein. Gynaecology : Professor Spiegelberg, five days weekly, 3. Psychology : Professor Neumann.

UNIVERSITY OF GETTINGEN,

The winter session begins on October 15, 1874, and ends on March 14, 1875.

Anatomy.—Professor Henle : Bones and Ligaments, Tues., Fri., Sat. 11 ; Systematic Anatomy, daily, 12 ; Topographical Anatomy, Mon., Wed., Thurs., 2 ; Dissections (with Dr. von Brunn, Prosecutor), daily, 9 to 4. Professor Krause : Normal Histology, 11 ; Pathological Histology, 12 or 2, each four times weekly. Dr. von Brunn : Exercises in Normal Histology.

Physiology.—Professor Herbst : General and Special Physiology, with Experiments and Microscopic Demonstrations, six days weekly, 10. Professor Meissner : Experimental Physiology of the Nervous System and Organs of the Senses, daily, 10 ; Researches in the Physiological Institute.

General Pathology.—Professor Krämer : General Pathology and Therapeutics, Mon., Tues., Thurs., Fri. 4 (or at other hours). Pathological Anatomy, Tues. and Fri. 2, Wed. and Sat., 12. Professor Marmé : General Pathology and Therapeutics, four times weekly, 6. Professor Meyer : Malformations of the Skull, once a week.

Materia Medica.—Professor Marx : Pharmacology with Prescriptions, Mon., Tues., Thurs. Fri., 2. Professor Marmé : Materia Medica, and Prescribing, with Demonstrations of Drugs and their Physiological and Toxic Action, four times weekly, 5 ; Electro-Therapeutics with Practical Exercises on Healthy and Diseased Persons, three times weekly, 2. Professor Husemann : Materia Medica with Demonstrations and Pharmacodynamic Experiments, five times weekly, 5 ; Repetitions on Materia Medica, with Instructions in Prescribing, Tues., Thurs., Fri., 2. Professor Wiggers : Pharmacy, six days weekly, 8. Professor von Uslar : Pharmacy, four days weekly, 4. Dr. Stromeyer : Pharmacy.

Forensic Medicine, Toxicology, and Public Health. Professor Marmé : Selected Chapters of Experimental Toxicology, Fri., 6. Professor Husemann : Narcotic Poisons, Mon., 2. Professor Krause : Forensic Medicine for Medical and Legal Students, Wed. and Sat., 4. Professor Meissner : Public Health, Mon., Wed., Thurs., 5.

Special Pathology and Therapeutics.—Professor Hasse : Lectures, Tues., Wed., Thurs., Fri., 4. Professor Krämer : Diseases of the Skin, and Syphilis, three times weekly.

Surgery.—Professor Baum : History of Surgery, Wed., 5 ; Surgery, five days weekly, 6, Sat. 3. Professor Lohmeyer : General Surgery, four times weekly, 3 ; Operative Surgery, four times weekly, 5. Dr. Rosenbach : Selected Chapters from General Surgery, once a week ; Repetitions on Special Surgery ; Operative Surgery, four times weekly, 5.

Ophthalmology.—Professor Leber : Practical Exercises on the Use of the Laryngoscope, Wed. and Sat., 12 ; Course of Operations on the Eye, twice weekly.

Obstetrics and Gynaecology.—Professor Schwartz : Midwifery, Mon., Tues., Wed., Thurs., and Fri., 3. Dr. Hartwig : Diseases of Lying-in Women, twice weekly ; Operative Midwifery on the Phantom, Wed. and Sat., 8.

Psychology.—Professor Meyer : Pathology and Treatment of Mental Diseases, Wed. and Sat., 3 ; Deformities of the Skull.

Clinical Instruction.—Medicine : Professor Hasse, Clinic and Polyclinic, daily, 10.30 to 12. Surgery :

Professor Baum, in the Ernst-August Hospital, daily, 9 to 10.30; Professor Lohmeyer, daily, 9. Ophthalmology: Professor Leber, daily except Sat., 12. Midwifery and Gynaecology: Professor Schwartz, Mon., Tues., Thurs., and Fri., 8. Psychology: Professor Meyer, Mon. and Thurs., 4 to 6.

UNIVERSITY OF LEIPZIG.

The Winter Session will commence on October 19, 1874, and end on March 15, 1875. The following courses of instruction will be given in the faculty of Medicine

Anatomy.—Prof. His: Human Anatomy (except the bones, ligaments, and vessels), daily, 2 to 4; Vessels, Mondays, 10; Dissections (with Dr. Rauber), daily, 8 to 4. Prof. Braune: Selected Chapters in Topographical Anatomy, one hour weekly; Bones and Ligaments, Wed. and Sat., 12; Dissections, for advanced students, daily, 2 to 7. Prof. Wenzel: Anatomy for Schoolmasters and other non-medical persons, Wed. and Fri., 6; General Human Systematic Anatomy (repetitions), Mon., Wed., and Fri., 5 to 7. Dr. Schmidt: Anatomy on the Living Subject, with reference to Surgical Diagnosis, Mon. and Thurs., 3. Prof. Rauber: Craniometry, Sat., 12; Histology, daily, 2 to 4. Prof. Ludwig (with Dr. Flechsig): Microscopical Demonstrations.

Physiology.—Prof. Ludwig: Sensation and Motion, four days weekly, 4; Physiological Exercises for advanced students; Physiologo-Chemical Exercises (with Dr. Drechsel); Physiological Demonstrations. Dr. Kronecker: Physiology of the Nerves and Muscles with reference to Electro-therapy, Wed., 7; Physiological Methods of Research, Fri., 5 to 7. Prof. Merkel: Physiology of Human Speech, Tues. and Fri., 3.

Hygiene.—Prof. Radius: Public and Private Hygiene, Wed. and Sat., 12. Prof. Hofmann: Hygiene, with Demonstrations, three hours weekly. Prof. Reclam: Hygiene of Towns and Dwellings, with demonstrations, Thurs. and Fri., 3; Public Sanitation, with experiments and demonstrations, Thurs. and Fri., 4; Exercises in Hygienic Research, Sat., 4 to 7.

Materia Medica.—Prof. Radius: Pharmacognosy, Mon., Tues., Thurs., and Fri., 12. Dr. Naumann: Pharmacodynamics, Mon. and Thurs., 6. Prof. Winter: Prescribing, with a sketch of the most important medicines, Wed. and Sat., 4. Dr. H. Herzel: Pharmacy (inorganic preparations) two hours weekly.

Pathology and Therapeutics.—Prof. Wagner: Special Pathological Anatomy, daily, 7.45 to 9; Exercises in Pathological Histology, two days weekly (with Dr. Trübiger); Pathological Demonstrations, according to opportunities, two months' courses; Researches in the Pathological Institute, daily, 8 to 12. Prof. Hofmann: Physiological and Pathological Chemistry, three times weekly, 2 to 4; Researches in the Pathologico-Chemical Laboratory. Prof. Thomas: Researches in Diagnosis, Sat., 3 to 5; Therapeutics, two hours weekly. Prof. Wunderlich and Dr. Baeltz: Auscultation and Percussion. Prof. Heubner: Pathology and Treatment of Local Diseases. Dr. Friedländer: Pathology and Treatment of Acute Constitutional Diseases. Dr. Furst: Pathology and Treatment of Diseases of Children, Mon. and Wed., 3. Dr. Hagen: Electro-Therapeutics, 7.

Surgery.—Prof. Thiersch: Lectures, four hours weekly. Prof. Braune: Operations with reference to Gunshot Injuries, Mon. and Thurs., 12. Prof. Schmidt: Orthopædic Surgery, Fri., 4. Dr. Schröter: Diseases of the Eye, three days weekly; Ophthalmoscopy, two hours weekly; Objective and Subjective Examination of the Eye, one hour weekly. Prof. Coccus: Ophthalmoscopy, Tues. and Fri., 6; Diagnosis and Treatment of Diseases of the Eye, Tues. and Fri., 7. Dr. Schön: Ophthalmoscopy, three hours weekly; Ophthalmiatric Researches, one hour weekly. Prof. Wendt: Lectures on the most important Diseases of the Ear, Nose, Fauces, and Larynx, with demonstrations. Dr. Hagen: Diseases of the Ear, two days weekly, 6; Laryngoscopy, Pharyngoscopy, and Rhinoscopy, two days weekly, at 7, in six weeks' courses.

Midwifery and Diseases of Women.—Prof. Germann: Diseases of Women, twice weekly, 7. Dr. Leopold: Pathology and Treatment of Diseases of Women, with demonstrations, four hours weekly; Obstetric Operations with Exercises, six hours weekly; Gynæco-Surgical Operations on the Dead Body. Dr. Haake: Deviations of the Uterus and their Treatment, one hour weekly; Special Chapters in Midwifery, two hours weekly; Repetitions in Theoretical Midwifery, three hours weekly. Dr. Ahlfeld, Theory of Midwifery, Mon., Tues., Thurs. and Fri. 5; Repetitions in Midwifery, including Exercises in Operations. Prof. Hennig: Repetitions in Midwifery, with Exercises on the Phantom, daily, 5. Prof. Crédé: Obstetric Demonstrations, Tues. and Fri., 3; Obstetric Operations with Exercises, Mon., Tues., Thurs. and Fri., 4, and Thurs. 3. Dr. Kormann: Obstetric Operations. Dr. Meissner: Theory and Practice of Operative Midwifery.

Clinical Instruction.—Prof. Wunderlich: Medical Clinic, in the City Hospital, daily, 9 to 10.30; Practical Exercises for Clinical Pupils, two hours (afternoon) weekly. Prof. Wagner: Medical Polyclinic at 2 daily, except Wednesday. Prof. Thomas: District Polyclinic. Prof. Thiersch: Surgical Clinic, daily, 10.30 to 12. Prof. Schmidt: Surgical Polyclinic, daily, 11. Prof. Coccus: Ophthalmic Clinic, daily, 12. Prof. Crédé: Obstetric and Gynaecological Clinic and Polyclinic, daily, 8, and 3 P.M. on Mon. Prof. Hennig: Children's Clinic, Mon. and Thurs. 9. Dr. Furst: Children's Polyclinic, Tues., Thurs. and Sat. 3. Prof. Merkel: Diseases of the Larynx (with Practical Exercises), Mon., Wed. and Sat., 3. Prof. Wendt: Diseases of the Ear. Dr. Hagen: Diseases of the Ear, daily, 11 to 1.

Forensic Medicine.—Prof. Sonnenkalb: Forensic Medicine for Law Students, Tues. and Fri., 4; Forensic Psychology, Wed.; Practice of State Medicine, Mon. and Thurs. 5 to 6.30. Prof. Reclam: Forensic Medicine with Demonstrations and Experiments, Thurs. and Fri., 6. Dr. Siegel: Courses of State Medicine. Dr. Meissner and Dr. Kormann: Forensic Midwifery, each two days weekly, at 6.

The following courses belong to the Philosophical Faculty.

Comparative Anatomy.—Prof. Leuckart: Comparative Anatomy, six days weekly, 12. Prof. Carus: Comparative Anatomy of Vertebrates, four days weekly, 10; Anatomy and Physiology of Domestic Animals, four days weekly, 12. Prof. E. H. Weber: Anatomy of the Nervous System of Fishes.

UNIVERSITY OF MUNICH.

The following courses of instruction will be given during the winter session, commencing November 3.

Anatomy.—Professor von Bischoff: General Anatomy, Myology, and Splanchnology, daily, 2; Dissections (with Professor Rüdinger), daily, 8 to 12, and 2 to 4, except Saturday afternoon. Professor von Hessling: Microscopic Examinations of Normal Tissues, three times weekly, two hours each time. Professor Kollmann: General and Special Histology, three times weekly; Use of the Microscope, three times weekly, 2 to 4; Anatomy for Artists. Professor Rüdinger: Bones and Joints, daily, 3, in first half session; Vessels, daily, 3, in second half session; Physical Anthropology.

Zoology.—Professor von Siebold, six days weekly, 1.

Physiology.—Professor Voit: Physiology of Nutrition, daily, 9; Exercises in the Physiological Laboratory; Researches in the Laboratory for advanced pupils. Professor Ranke (in the Philosophical Faculty): Lectures on Medical Physics with Practical Exercises, Mon., Tues., Wed., Thurs., 8; Experimental Physiology for advanced students; Human Physiology with reference to Anthropology, Mon., Tues., Wed., and Thurs., 3.

Pathology.—Professor von Buhl: General Pathology and Pathological Anatomy, Mon., Tues., Thurs., Fri., 10; Practical Pathological Anatomy (microscopic), Mon., Tues., Thurs., 11 to 12.30; Repetitions in Pathological Histology. Professor Bollinger: Selected Chapters in Comparative Pathology, with demonstrations, twice weekly.

Medicine.—Professor von Gietl: Physical Diagnosis, Mon. and Thurs., 4. Professor von Ziemssen: Special Pathology and Therapeutics, daily, except Sat., 5; Clinical Instruction in Physical Examination, Mon. and Thurs., 6 to 8. Dr. Brattler: Physical Diagnosis. Dr. J. Bauer: Physical Diagnosis, three times weekly; Diseases of the Kidneys, once weekly. Professor Hauner: Diseases of Children. Professor Bollinger: Parasitic Diseases.

Surgery.—Professor von Rothmund: Hernia, Wed., 4. Professor Nussbaum: Surgery, Mon., Tues., Thurs., and Fri., 4; Bandaging. Dr. Ruprecht: On Fractures, with regard to Military Surgery, twice weekly, 12. Dr. Schweninger: Practical Demonstrations of Surgical Anatomy on the Living Subject, twice weekly; Hernia, once weekly. Dr. Mayer: General Surgery, three times weekly; Aural Surgery, twice weekly. Dr. Posselt: Syphilis, twice weekly; Use of Instruments and Bandages. Dr. Oertel: Diseases of the Larynx and adjacent Cavities, twice weekly; Course of Laryngo-Rhinology. Dr. Schech: Pathology and Treatment of Diseases of the Larynx and Trachea, with a Course of Laryngoscopy, twice weekly. Professor Koch: Diseases of the Mouth and Teeth.

Ophthalmology.—Professor A. Rothmund, jun.: Ophthalmic Surgery, four times weekly, 6; Course of Ophthalmoscopy, Wed. and Sat., 6; Course on Diseases of Refraction and Accommodation.

Obstetrics and Gynecology.—Professor von Hecker: Theoretical Midwifery, five days weekly, 9; Obstetric Operations, four times weekly, 5. Dr. Amann: Theory of Gynecology, three times weekly.

Materia Medica.—Professor L. A. Buchner: Pharmacy, four days weekly; Chemical Exercises in the Pharmaceuto-Chemical Laboratory, daily, at

midday; Exercises in Dispensing, with Conversations on Drugs, four evenings weekly. Professor Seitz: Materia Medica and Prescriptions, five days weekly, 11. Professor J. Buchner: Comparative Materia Medica and Pharmacotechnics, 7. Dr. von Böck: Action of Medicines, with Experiments; Art of Prescribing, with Practical Exercises, once weekly.

Hygiene.—Professor von Pettenkofer: Practical Instruction in the Hygienic Laboratory, daily; Lectures on the Mode of Diffusion of Typhus, Cholera, and Yellow Fever, Wed. and Sat., 10 to 12. Dr. Forster: Articles of Food and their Adulteration, once weekly.

Forensic Medicine, etc.—Professor Martin: Forensic Medicine, four times weekly; Practical Instruction, daily, 11.

Clinical Instruction.—Medicine: Professor von Gietl and Professor von Ziemssen, daily, 9. Professor von Ziemssen: Clinical Conversations, once weekly, 8 to 10 P.M. (class limited in number.) Professor Seitz: Medical Polyclinic, daily, 12. Surgery: Professor von Nussbaum, daily, 8. Dr. Mayer: Surgical Polyclinic; Demonstrations on Patients. Obstetrics and Gynecology: Professor von Hecker, Midwifery Clinic, four times weekly, 10. Midwifery Polyclinic: Dr. Amann, Gynecological Clinic and Polyclinic, three times weekly. Diseases of Children: Dr. Hauner; Dr. H. Ranke, daily, 3. Psychology: Dr. Gudden, Wed. and Sat., 4 to 6. Ophthalmology: Professor A. Rothmund, jun., daily, 11. Syphilitic and Cutaneous Diseases: Dr. Posselt, twice weekly.

UNIVERSITY OF WÜRZBURG.

The entries for the winter session will commence on October 15; the lectures will begin on November 3.

Anatomy.—Professor von Kölliker: General Anatomy, Muscles, and Intestines, Tues., Wed., Fri., and Sat., 11 to 1; Normal Histology, Tues. and Fri., 6 to 8; Dissections, with Dr. Wiedersheim. Dr. Wiedersheim: Bones and Ligaments, three hours weekly. Dr. Gierke: Microscopic Anatomy, and Physiology of the Central Nervous System, three times weekly.

Physiology.—Professor Fick: Special Physiology, Mon. and Fri., 10; Physiological Exercises and Researches.

Pathology.—Professor Rindfleisch: General Pathology, daily, except Wed., 11; Course of Demonstrations and the Use of the Microscope, daily, except Wed., 2; Practical Pathology in the Institute.

Medicine.—Professor Gerhardt: Medical Clinic, six days weekly, 9; Special Pathology and Therapeutics, five days weekly, 5. Dr. Stöhr: Special Pathology and Therapeutics, five times weekly; Repetition on Internal Medicine, six times weekly; Course of Clinical Diagnosis; History of Medicine, twice weekly. Dr. Rossbach: Physical Diagnosis, Tues. and Thurs., 6. Dr. Emminghaus: Physical Diagnosis, five times weekly.

Surgery.—Professor von Linhart: Surgical Clinic, six days weekly, 10; Course of Operative Ophthalmic Surgery, 3 to 5. Professor Dehler, Theory of Surgery, daily, 3. Dr. Riedinger: Fractures and Dislocations, three times weekly; Clinical Course of Surgical Diagnosis, four times weekly.

Ophthalmology.—Professor Ritter von Welz: Ophthalmic Clinic, with Ophthalmological Examina-

tions, Tues., Thurs. and Sat., 11; Course of Operations on the Eye, Mon., Tues., Thurs., Fri., 2; Lectures on Ophthalmic Operations, once weekly. Dr. Helfreich: Ophthalmology with Clinical Demonstrations, four times weekly; Ophthalmotropy with Practical Exercises, twice weekly; Course of Operations on the Eye.

Diseases of the Ear.—Professor Baron von Tröltzsch: Pathology and Treatment of Diseases of the Ear, three times weekly.

Dental Surgery.—Professor Ritter von Welz, three times weekly.

Midwifery and Diseases of Women.—Professor Scanzoni von Lichtenfels: Obstetric and Gynaecological Clinic, five times weekly, 12; with Exercises in Examination, twice weekly, 8. Dr. J. B. Schmidt: Course of Obstetric Operations. Professor Müller: Theory of Midwifery, five times weekly, 4.

Chemistry, Materia Medica and Toxicology.—Dr. Schubert: Pharmaceutical Chemistry and General Chemistry, each four times weekly. Dr. Rossbach: the Theory of Medicines and Poisons, with Experiments on Animals, Mon. and Wed., 6; Fri. 6 to 8; Introduction to Practical Pharmacy, daily, 2 to 7.

Psychology.—Professor von Rinecker: Psychological Clinic, three times weekly, 5; Diseases of the Mind, twice weekly, 11. Dr. Emminghaus: Forensic Psychology, twice weekly; Diseases of the Brain, once weekly.

Special Subjects.—Professor von Rinecker: Clinic for Syphilis and Diseases of the Skin, three times weekly, 11; Diseases of the Skin, once weekly.

THE PROPHYLACTIC TREATMENT OF CHOLERA. By PROFESSOR LEBERT OF BRESLAU.

(Continued from page 597.)

Disinfection during the Prevalence of Cholera.—I confine myself here to the most important points on this subject. Much has been said concerning disinfection, both for and against. Some look upon cholera excreta as the proper poison-carriers, others regard the excreta as incapable of contagion. Some have a blind belief in the protection afforded by these agents against infection, others deny them any value whatever. If anyone would discover cause to leave the whole course of the disease to chance, because of the difference of opinion concerning this as on nearly all the questions of cholera, he would commit a great and a most deplorable mistake.

Physicians are almost unanimous in the belief that a specific organic germ lies at the basis of cholera. The opinion gains ground from day to day that this germ is not only organic, but also organised. Whether this germ, which has entered the organism of the individual attacked directly or indirectly from the earth, water, privies, vaults, etc., is to be sought in the excreta or other emanations or not, physicians are mostly unanimous in believing that patients may in some way or other assist in disseminating the disease.

It must be the continual effort of science, therefore, to prevent as much as possible the injurious action of the cholera-germs before or after their entrance into the human organism. Convinced of the value of disinfection in this regard, I shall now bring forward the most important points concerning it from a practical point of view.

Above all things it is essential to make a distinction between disinfection in treatment and the

common antiseptic methods employed in the trades. A much greater quantity of disinfecting material is necessary to destroy exuberating germs than to prevent their development; a series of new experiments have fully convinced me of this fact. The small quantities which suffice to prevent sepsis in solid and fluid foods by no means suffice to disinfect infected substances, fluids, etc. The work of disinfection is to destroy the germs or lower organisms already developed in considerable numbers, and if preventive disinfection shall have been extensively practised before the outbreak of an epidemic a decided advantage will have been gained. Another important preliminary point is this: there is a great and not sufficiently recognised difference between disinfection and the destruction of odours. The destruction of odour reaches only a few of the products of fermentation, of decomposition and infection. True disinfection should reach the cause, the fundamental basis of all these processes.

Who shall take charge of the disinfection? Best the authorities, and in the most rigid way, assisted, perhaps, by those who are in any way independent enough in circumstances to be able to share the costs. Disinfection is never so generally and thoroughly carried out by private parties as to be of any real protective effect. But there are numerous instances where large cities have been most successfully disinfected by the authorities.

I will now make a few comments upon the agents of disinfection, taking them in the order of efficiency, and I commence with the best and most potent.

1. *Carbolic acid* or phenylic acid is the best antiseptic and antimycetic agent of all the well-known and thoroughly tested means. Water which contains carbolic acid in the proportion of 2 per cent. will destroy great quantities of protomycetic masses. The pure acid, unmixed with any of the numerous substances suggested, is by far the best and most to be recommended. It is comparatively costly, but is more reliable than any of the cheap disinfecting substances. Its permanent odour in houses and dwellings is disagreeable, but one soon becomes accustomed to it. For large accumulations of excreta, privy-vaults, etc., 200 to 250 grammes of the acid should be dissolved in 3-4 litres of water and poured in once a day, best with a watering-pot. For privies 100 to 200 grammes suffice, for large night-stools 30 to 50 grammes a day, and for night-vessels during the disease, a few grammes from time to time. The floor of the room should be sprinkled every day with a 2 per cent. solution to attack the germs floating in the air, and if the room be always moist the solution may be mixed with sawdust, which should not be made too wet, however, and then after strewing the floor the room should be swept out or cleaned up. The washing may also be sprinkled with the same solution before it is put into boiling water. The heat of the bake-oven, about 100° C. (212° Fahr.), should be selected for linen, which will not bear boiling water, and this dry heat is also the chief means of disinfection of mattresses, garments, etc. Less valuable materials, as straw beds, etc., are best burned up, and one should not be too economical in this regard in cholera times. Küchenmeister's suggestion to burn up the excreta with fine and dry sawdust is most especially to be recommended.

2. *Sulphurous acid* has hitherto found but little application in cholera, although its fumes have long been employed in numerous ways for the destruction of parasitic germs and organisms. As vaults, privies,

vessels, etc., cannot be disinfected with pure sulphurous acid, I made a series of experiments with water impregnated at 2 per cent. Even minimal quantities (1-10,100th) suffice to arrest the development of protomyceta, though a 2 per cent. solution is necessary to destroy them when already luxuriating in growth. This solution holds for weeks without any alteration in the degree of oxidation of the sulphurous acid. Its penetrating odour is only transitory. It is easy to make a 2 to 4 per cent. solution of sulphurous acid in great quantity, and it is cheaper than any other disinfecting agent. From one to several litres of this fluid may be used daily for vaults, privies, and 50 to 100 grammes for night-stools and small vessels. Disinfection of the washing and bedding material may be accomplished by the development of fumes of sulphurous acid from burning sulphur in perfectly close rooms after previous sprinkling with the solution mentioned. My suggestion of using water impregnated with sulphurous acid, as in Lister's bandage, for the prevention and treatment of infection of wounds by bacteria, has not been subjected to the test of experience. My experiments with it, however, justify the hope that we may possess in it a potent, cheap, and easily applied method of disinfection for a wide range of cases.

3. *Green vitriol*, the sulphate of the oxide of iron, had at one time a great but only ephemeral reputation as a disinfectant. We have become convinced, however, that it is more potent in disguising bad odours than in energetically attacking the germination of parasites. Its oxidation of organic combinations does not lead to the destruction of injurious myceta. The more this agent was used, the more have its combinations with carbolic acid, permanganate of potash, etc., increased, a proof that its universal antiseptic action has been more and more distrusted.

4. *The permanganates* develop a rapid but quickly vanishing disinfectant and parasiticide action; hence it has been recommended in multiform combinations with sulphate of iron, chloride of lime, etc. I cherish a distrust against all compound disinfectants, as it seems to be imagined that any uncertainty of action on the part of individual substances will be relieved by a multiplication of agents or by chemical combinations; theories which rest, for the most part, on uncertain or obscure conceptions.

5. *Chloride of lime* is one of the oldest but certainly not one of the best disinfecting agents, notwithstanding its continued official character. It destroys bad odours, but affects but little the germs and seed of parasites. Its odour, if developed in sufficient quantity, is only partially parasiticide at most, is as unhealthy as disagreeable, and is even at times injurious.

The same uncertainty of action pertains to *Süvern's* disinfectant, which consists of a mixture of lime, magnesium, chloride and tar, and of lime and coal.

Carbolic acid is therefore the best means hitherto known for disinfection of the air, of excreta, sink-holes and privies. The efficacy of sulphurous acid water remains still to be proven. A boiling heat is the best method of destroying the dangerous germs in drinking-water. The washing, bedding, and clothing are most thoroughly disinfected, besides, by fumigation with sulphur or sprinkling with carbolic water, by dry heat in ovens, and by maceration in boiling water when the quality of the material admits it.

Individual Protection.—It is generally believed that the fear of cholera predisposes to it. My experience

does not confirm this view, as I have found that the greater the fear, the more minutely are all the precautionary measures adopted. These are, above all things, of hygienic nature, and the apparent effect of preservative agents depends upon the well-known affinity existing between charlatanism and credulity. The most favourable hygiene plays here the chief rôle; avoidance of cold, disturbances of digestion, errors in diet, excesses of every kind, mental disquietude, in a word, observance of moderation and caution of every kind. The accustomed mode of life, if normal and rational, should be by no means changed. But the vegetables whose abundance of water might easily induce diarrhoea, as cucumbers, melons, etc., should be taken more cautiously and in less quantity. Of course all unripe vegetables or those inclined to decay, all drinks of not perfectly normal quality, are strictly to be avoided. A good animal diet should be ordered for feeble and sickly patients, with old wine, the addition of a little rum or cherry-water to the tea; the feet and body should be kept warm by flannels, if the circumstances of the individual permit these comforts. Among the poorer classes small quantities of brandy may take the place of the wine, and where the diet cannot be substantial, good, warm, nutritious soups and hot coffee may be recommended. The physician must of course advise his patients, especially in cholera times, according to the circumstances of individual cases. It is on this account that soup and other eating-houses should be carefully organised, on the most extensive scale possible, before or at the beginning of an outbreak of the disease. Thorough, regular, and abundant disinfection is an integral factor in individual protection. Useless contact with patients or unnecessary visits to houses where cholera prevails should be avoided, unless it is a case of near relationship, or unless the individual, on account of his avocation or from motives of philanthropy, willingly exposes himself to danger which the greatest care will not always exclude. Among the never-to-be-forgotten suggestions for individual protection is the advice to treat properly, or have treated, every form of diarrhoea, no matter how light. I learned the exceeding value of this and other prophylactic suggestions in a large practice during the fearfully murderous epidemic in Paris, 1849. There is no time when the physician may prove himself a friend to the family in such degree as during the prevalence of an epidemic of cholera.

When a number of cases have occurred in a house, the remaining inmates should be advised to leave it. The poor should go to the previously arranged houses of refuge, the wealthier to a residence in another part of the city or to another place in the country for a few weeks, but always instructed with all the suggestions which may prevent the development of cholera in the places visited. All who are very fearful of the disease, and who may be able to leave the infected locality, should do so as early as possible, alone or with their families, but always instructed of course as to the best means of prophylaxis.

PATHOLOGY.

RAYMOND AND VULPIAN ON THE PATHOLOGY OF JAUNDICE.—*Le Progrès Médical*, in reporting the proceedings of the Société de Biologie of Paris

(July 13, 1874), gives the following abstract of M. Raymond's paper. M. Raymond stated that he had observed an interesting fact throwing light on the pathology of jaundice, in two phthisical patients under the charge of M. Vulpian. In his pathological course, M. Vulpian, wishing to elucidate the various methods in which jaundice originates by means of experiments, remarked that, next to obstruction by biliary calculi, the most common form of jaundice is that produced by swelling of the mucous membrane of the biliary passages, the so-called catarrhal jaundice; also that Broussais believed in an extension of the inflammatory process, in what he called gastro-duodenitis. However, his theory was not popular, and it became the fashion to attribute the jaundice to hepatic congestion; but Virchow confirmed Broussais, showing that the obstruction in these cases was caused by a plug of mucus very near the duodenal opening of the common bile-duct. M. Vulpian added, 'I have twice seen this in men, and have very often verified it in the dogs on which I experiment.' This propagation of duodenitis to the biliary passages is very common in dogs, and it often happens that a number of symptoms are set up, like those collectively known under the name of black or malignant jaundice (*ictère grave*); the dog dies with hæmorrhage and ataxo-adyamic symptoms.

The first of M. Raymond's cases was an old woman of sixty-four, who was in the third stage of phthisis. She had been in the hospital from November 10, and the disease followed its usual course, till January 15, when she was attacked with the most intense jaundice. The coloration was most marked in the skin, the conjunctivæ, and the lower surface of the tongue. Her urine contained a large quantity of bile-pigment, and the jaundice lasted till her death, three days afterwards.

The second case was a young woman aged twenty-six years, also phthisical, who was admitted an in-patient in September 1873; she became yellow on February 22. Like the first case, her jaundice was general. The feces were almost colourless, the urine contained bile-pigment largely, and the patient died four days afterwards. The results of *post mortem* examination were identical in both cases, except as regards the thoracic lesions. The gall-bladder was full of fluid; there were no gall-stones; the bile-ducts were moderately distended. On opening the duodenum, and pressing upon Water's papilla, some drops of thick mucus escaped, glutinous, and resembling bile in colour: the bile-ducts were healthy, except that their walls were swollen; there were no granulations, nor induration, and they were not compressed by any swollen glands. The duodenum was thickened and red; at its lower portion Brunner's glands were seen to be hypertrophied, and to have the appearance of grains of rice, giving the mucous membrane a resemblance to shagreen. Here and there its membrane was still more raised, though slightly, probably from hypertrophied follicles. Microscopic examination, in the recent state, demonstrated very active congestion of the vessels of the mucous membrane of the duodenum. On examining Brunner's glands, their acini were found enlarged; and they were filled with swollen epithelial cells. Sections made perpendicularly to the mucous membrane, after suitable handling, showed still more plainly the multiplication of the epithelial elements in Brunner's glands, and in some preparations the solitary glands were found to be increased in size. It was thus clear that, in

both these cases of duodenitis, the inflammation had reached the ductus choledochus, which was obstructed by a plug of mucus, whilst the retention of bile thus induced had brought on jaundice. The reaction against Broussais' views has gone too far in denying the existence of duodenitis, for it really exists. Broussais' mistake lay in exaggerating its importance.

At the same sitting M. Poncet (of Lyons) made some remarks on hæmatic jaundice, and narrated his experiments on the urine of patients attacked with icterode coloration, as a sequel of large losses of blood. He has made many experiments on animals. After injecting blood into the subcutaneous areolar tissue in dogs, he has seen the urine also become reddish brown. This colour is due to an excess of urinary pigment, in consequence of the destruction in the tissues of a great number of red blood-corpuscles. In these cases there was no increase of bile-pigment.

W. BATHURST WOODMAN, M.D.

BENEDIKT ON THE ANATOMICAL CHANGES IN HYDROPHOBIA CANINA.—The long-continued epidemic of last winter has, through the assistance of his colleagues of the Imperial Veterinary School in Vienna, furnished Dr. Benedikt (*Wiener Mediz. Presse*, June, 1874), with numerous preparations from the brain and spinal cord of different animals that had been attacked with rabies. Before describing these, the author discusses the difference presented by the disease as seen in man and in dogs, which has also a special significance with reference to the anatomical appearances. In both the disease begins with a restless melancholia. In the dog this passes into raving madness, while in man this form of mental affection is wanting. In man illusions and hallucinations take but small share in the symptoms, while in dogs they are plainly a prominent feature. In man there is the greatest degree of hyperæsthesia, with highest possible susceptibility for convulsions; in dogs, diffused paralysis and aphonia are among the earliest and characteristic symptoms. In the human being there is the most extreme reflex excitability in the movements of deglutition, so that not only the raising a glass to the mouth, but even the sight of fluids, will induce violent spasmodic action in those organs; whereas in dogs there is a paralysis of deglutition for fluids. In man the severest spasms of the respiratory muscles are present, so severe as sometimes to cause asphyxia. Such spasms are not observed in dogs, which die generally from exhaustion.

Dr. Benedikt has studied the pathological changes by making seven separate vertical sections through the hemispheres in dogs, and has observed such plain and striking pathological changes as could, he observes, only have been previously overlooked by reason of an imperfection of the methods of investigation.

In the first place, there is noted an abnormal distension of the meningeal vessels, and the accumulation around them, and in the meshes of the pia mater, of inflammation-corpuscles, together with a nucleolated exudation. This exudation is strongly refractive of light, is colourless, and under high magnifying powers is seen to consist of punctiform nuclear substance (granular disintegration). Striking changes are observed in the grey matter of the convolutions, and in various parts of the nervous centres. One of the coarser changes observed was the presence of numerous holes, or spaces, which, when magnified eighty or ninety diameters, were seen to

be filled with a material which also refracted light. This mass, under the high powers of the microscope, consisted of a granular or nuclear substance, in which were single hyaloid and colourless corpuscles, of the size of a distended nucleus of a blood-corpuscle. Inflammatory corpuscles were to be seen in both these masses. In the larger spaces, nerve-cells also were found. Dr. Benedikt further describes what he calls a peculiar condition of the hardened brain, especially in the finer sections. The slightest pressure forced out upon the surface shining masses, which under the microscope proved to be myelin (colloid? *Rep.*). These masses were often found lying detached on the surface of the section, and presented a greenish lustre. The author states that he has seen the same in the spinal cord of a horse that had suffered from rheumatic tetanus, and that he had regarded it as a softening and chemical alteration of the substance of the spinal cord.

The signs of inflammation are not presented everywhere in the pia mater, but only in certain parts. The distribution of these in the grey matter and in the central white substance throws a new light, according to Dr. Benedikt, upon the nature of the 'granular disintegration.' (A diagram intended to illustrate this point is given.) From what he has noted, it is concluded that the pathological process in this disease consists in acute exudative inflammation, with hyaloid degeneration, which doubtless arises from the exudative infiltration of the connective tissue. It is characteristic with reference to these inflammatory products that the attack, in man at least, is ushered in with rigors. The hyperæmia and nuclear proliferation is concurrent with that form of diffused inflammation which Lockhart Clarke has designated as 'granular disintegration,' and so far, the author considers, the anatomical obscurity of this disease is dispelled. The morbid process, in man, is doubtless essentially the same. The usual *post mortem* appearance is congestion and softening, which may have no especial value except as following asphyxia.

Dr. Benedikt states that there are in literature only two trustworthy reports, viz., by Meynert, who found much the same appearances as the author. The spaces, or holes, are regarded by Meynert as being the result of the hardening of the brain-substance. In two other cases Meynert found hypertrophy of the connective tissue in the posterior columns, with molecular and amyloid degeneration in the anterior columns. The nerve-cells of the cortical matter had also undergone partly molecular, and partly sclerotic change.

W. B. KESTEVEN.

RAYNAUD ON PSEUDOMEMBRANOUS ENTERITIS.—M. Raynaud (*Le Progrès Médical*, p. 413) describes a case in which some fragments of membrane were passed by a woman, sixty years old, with cardiac disease. The woman had experienced no colicky pains; whereas in the cases reported by M. Siredey, the persons had suffered most intense pains, almost as severe as labour-pains, and in all similar instances reported it was just the same. One of the pieces was more than a yard long, and might have been mistaken for a tapeworm. It was a hollow cylinder, closed at its ends by a flattened piece of membrane. Its external diameter was nearly a centimètre, its internal one about five millimètres. The microscope showed traces of mucine, and a consider-

able quantity of leucocytes. The discharged matters were, in fact, concretions of intestinal mucus. How they were formed is difficult to explain; but M. Raynaud thinks it reasonable to suppose that they were the result of a deposit of mucus on the inner coat of the intestines, which, becoming detached, were by the peristaltic action of the bowels formed into tube-like bodies. In the discussion which followed the presentation of the specimen, M. Debosc thought that gradual contraction of the tube took place after its detachment from the intestine. M. Carville, from his experience of the peristaltic action observed in animals, could not believe that the tubes were formed as M. Raynaud suggested.

SURGERY.

RÉLIQUET ON OBSTRUCTION OF THE LEFT EJACULATORY DUCT BY CONCRETIONS FROM THE VESICULA SEMINALIS (SPERMATIC COLIC).—M. Réliquet relates in the *Gazette des Hôpitaux*, September 3, 1874, the case of a hairdresser, aged thirty-five, married, pale, thin, delicate, and exhausted-looking, who consulted the author on March 12, 1874. For several years he had often suffered, when at stool, from the emission of a small quantity of thick white liquid. For two months he had experienced pain, extending from the anus to the perinæum, on emissions during coitus or when emptying the bowels. The erect posture and walking provoked frequent micturition. Attempts to retain his urine caused acute pain and cold sweats. The pain lasted four or five minutes after urination. He lost desire to sleep. Venereal desires and erection provoked pain. During one month and a half he had passed small quantities of blood with his urine.

On March 12, a gum elastic bougie (French, no. 20) was passed easily into the bladder, but caused excessive pain in the deep part of the urethra. He was sounded for stone the next day, but no foreign body was discovered in the bladder. On examination from the rectum, the left vesicula seminalis was found swollen, hard, and smooth. It was painful on pressure. After the sounding, an attempt was made to pass the bougie once more, but the instrument was arrested at the neck of the bulb, and then withdrawn. After two or three minutes of extremely sharp cutting pains in the penis and the anus, the patient stooped down, and, emptying the bladder, expelled as many as forty small opaque white bodies, about the size of a small pin's head or a lentil. They presented facettes and blunt angles, like prostatic calculi, but their consistence was soft, and they could be crushed between the fingers. To the naked eye, they appeared to be formed of a white homogeneous material devoid of any capsule.

After the passage of these bodies, the symptoms quickly subsided, and, on examining from the rectum on the third day, the left seminal vesicle was found of the same size as the right.

On March 27 the man had returned to his usual occupations, and only had to pass urine twice in the night.

Professor Robin, who examined the concretions, sent M. Réliquet the following report. The concretions, opaline, transparent, had a diameter of from one to two millimètres. Their substance, under the

microscope, was marked by very fine and very short rectilinear striæ, parallel, closely approximated to each other. Acetic acid caused the striated condition to disappear, and rendered the substance quite translucent, and homogeneous. At the same time it demonstrated numerous spermatozooids rolled together in the concretions formerly marked by the striæ. Where the striation was absent or scarcely marked on the concretions, which were of various forms, such as M. Robin has shown in the vesiculæ seminales of many healthy individuals (Charles Robin, *Leçons sur les Humeurs*, Paris, 1874, 2nd edition, p. 443), these bodies had the aspect of normal ones. They had similar reactions to acetic acid, reactions which were not only those of mucus. Their volume was enormous, compared with that of the concretions in normal vesiculæ, and their consistence a little greater. But, they only represented normal corpuscles, which had accidentally attained gigantic proportions, and englobed the spermatozooids in the ordinary way.

Réliquet insists much on these facts in making the diagnosis; 1. That the first pain is produced suddenly at the time of coitus; 2. That subsequently every erection, or even every desire for coitus produces pain. They are, he says, the subjective symptoms. These combined with the objective signs, especially with the uniform swelling of the seminal vesicle, should lead to a correct diagnosis.

JOHN CROFT.

LINCOLN ON RETROPHARYNGEAL ULCERS CURED BY EXTERNAL ASPIRATION.—Dr. Lincoln, of New York (*New York Medical Record*, September, 1874), relates a case in an infant, five months old, in which he opened a large pharyngeal abscess with a guarded bistoury. As it formed again with considerable swelling externally, he, by means of the pneumatic aspirator, emptied the abscesses. This operation was performed four times on the right side, and three times on the left, with perfect success, no external mark being left behind.

STEURER ON A NEW ASPIRATOR.—The instrument is meant to obviate the danger of wounding any internal vital organ whilst the fluid is being drawn off, and also to be able to clear the cannula whilst the instrument is *in situ*. It consists of a glass cylinder, of a capacity of eight ounces, with a piston-rod worked with a rack by means of a key. The rack apparatus can be removed without affecting the instrument, and it can be worked as an ordinary syringe. There is a stop-cock to inlet and outlet, fixed at the base of the cylinder. The trocars are screwed on a rod, which is placed in a tube and passes through a cap of India-rubber packing, so that the more the cap is screwed down the tighter the packing becomes. The cannulæ are screwed on to this aforesaid tube; different sizes of trocar and cannula can be used to the same instrument. The trocar is withdrawn as soon as it has been inserted deep enough, and in case of any plugging it is pushed down so as to free any obstruction. The apparatus is made by Messrs. Siemen and Co. It has been used many times with success.

W. C. GRIGG, M.D.

OPHTHALMOLOGY AND OTOTOLOGY.

HOSCH AND SATTLER ON SEROUS CYSTS OF THE IRIS.—In Zehender's *Klinische Monatsblätter für Augenheilkunde* for April and May, Dr. Hosch of Basel and Dr. Sattler of Wien, have papers on the serous cysts which occur in the iris. The theories given as to their origin are discussed, that of Von Wecker being that all such cysts have their origin from the folding in and attachment of such folds of the iris, either with or without a wound in the cornea; while Rothmund holds that they have their origin only by the carrying of corneal epithelial cells into the iris, after or during the infliction of a corneal wound, and that these cells increase in their new position, secrete, and so form a cyst within the iris-tissue itself. Dr. Hosch describes the microscopic anatomy of an eye, in which an iris-cyst had occurred after a wound, and which was removed on account of sympathetic ophthalmia of the other eye. The cyst was about five millimètres deep, lying in the tissue of the iris on the one side, while on the other side it was bounded by the ciliary body, sclera, conjunctiva, and cornea. He thinks there had been a division in the iris-tissue arising from a wound at the corneo-scleral junction, which, after the consequent collapse of the anterior and posterior chambers, and the soldering of the anterior and posterior surfaces of the iris to the neighbouring tissues, had been, on the closure of the anterior wound, filled by the re-accumulation of the aqueous humour, and so formed the cyst. He considers that the case goes to support Von Wecker's theory as to the origin of such cysts.

Dr. Sattler had the opportunity of making microscopic examinations of three such cysts, and found that in all three the wall was composed of fibrous tissue, with a lining of large flat cells, consisting of several layers. In these cases, he believes he established the following facts:—1. The preceding of, and in itself, a trifling wound; 2. The presence of a cicatrix at the corneo-scleral boundary; 3. The commencement of the cystic formation long after the wound; and 4. The after-appearance of irritable conditions by the increase of the cyst, and the clothing of its inner surface by a variedly thick layer of flat cells. He thinks that the elements of these epithelial layers not only increase by division of the epithelial cells present, but receive additions from the cells in the stroma. In one case he found what he calls an anatomical peculiarity, capillaries in the wall of the cyst. Dr. Sattler is not fully satisfied with any already proposed theory of origin.

CASSELLS ON CASES WHICH SUGGEST SOME PROBLEMS IN OTOTOLOGY, AND QUESTIONS IN AURAL PATHOLOGY.—Dr. Cassells gives in the *Glasgow Medical Journal* for July, notes of seven cases on which he purposes making comments in a future communication. One case is somewhat remarkable. A young woman, aged twenty-five, suffering from purulent tympanitis, had removed from the left tympanic cavity what proved to be the whole cochlea in a necrosed state, and yet afterwards heard a watch one inch from the ear, and 'with apparently undiminished distinctness, the transmitted tones of the diapason, and all the tones as well as semitones, of the piano, the right ear during this latter experiment being closed effectively to the entrance of sound.' While under observation, she

THE annual congress of the Association of German Naturalists and Physicians has just been held in Breslau, in Silesia. It has been decided to hold the meeting in 1875 at Gratz, in Bohemia. The Association meets alternately in North and South Germany, the latter term including the Austrian dominions.

was subject to tinnitus, 'much giddiness,' frequent vomiting, and inability to keep the perpendicular position, the tendency to fall being towards the left side, but these symptoms were less marked when last seen.

W. LAIDLAW PURVES.

WECKER ON TRAUMATIC RUPTURE AND DISPLACEMENT OF THE INTERNAL RECTUS MUSCLE: ITS REPLACEMENT BY A DOUBLE SUTURE.—In the *Annales d'Oculistique* for May and June, 1874, Wecker reports an interesting case in which the internal rectus had been completely torn from its insertion to the eyeball, and had retracted so as to cause a divergent strabismus, and an annoying amount of diplopia.

The patient, a man aged forty-two, had fallen with his face upon the handle of some kind of beer-tap, and had received a contused wound at the inner angle of the eye, by which the internal rectus had been torn through. The consequences were a divergent squint of 3" or 4", and a distressing amount of crossed diplopia. Some time after the accident, and when the parts were soundly healed, M. Wecker replaced the detached muscle by sutures, and was fortunate enough to obtain a complete cure.

The scar in the conjunctiva was firm, and required very careful dissection from the eyeball; the muscle was exposed and brought forward, and then attached to its old insertion by two threads which were made to cross each other before they were tied, a method of securing them which M. Wecker strongly recommends as calculated to ensure thorough fixation with less strain upon the muscle itself. The result of the operation, which, though necessarily tedious and painful, was borne without chloroform, was the complete removal of the squint and cure of the diplopia.

BOWATER J. VERNON.

TOXICOLOGY.

RAYMOND ON POISONING BY OSMIC ACID.—All inquiries into the toxicological action of the rarer metals have a peculiar interest. The deleterious action of osmic acid has been known for a long time. M. Frémy was the first to call attention to the poisonous nature of the osmium compounds. M. Sainte-Claire Deville was himself seized with persistent nervous asthma in working with the acid. M. Debray suffered from some affection of the eyes caused by it; and lastly, M. Julien Clément found that it induced a cutaneous disease which was very difficult to cure.

The paper before us in *Le Progrès Médical* of June 27, 1874, gives a history of a case of supposed poisoning by osmic acid. A man aged thirty, being out of his usual employment (a band-box maker) engaged himself to work in the laboratory of M. Sainte-Claire Deville. Here he was occupied in the daily handling of pieces of osmium, platinum, and iridium. In the process to which they were subjected, an osmate of baryta was produced; this was treated with nitric acid, and the osmium precipitated with sulphide of ammonium. The man up to the time of beginning this work was perfectly healthy, and it is important to notice there was no history whatever of syphilis. After commencing this new employment he was very soon taken ill, the first symptom of which he complained being pains in the eyes. He slept heavily at night, and was much

troubled with nightmares. After a few days, an extensive eruption appeared on the surface of the forearm, on the face, and on both sides of the hands. Extreme indigestion, frequent diarrhoea, nine or ten times daily, and at each stool the passing a considerable quantity of black blood (the patient having no signs of piles) were prominent symptoms as the case progressed. Violent headaches, nausea without vomiting, shiverings, extreme dyspnoea, and a harassing cough rapidly followed. On admission at the hospital, the one prominent symptom was the extreme difficulty in breathing, amounting almost to threatening asphyxia. The temperature was 104° Fahr. On examination, the chest revealed the existence of a general bronchitis, and on the left side there was a somewhat extensive pneumonia. The skin of the hands and forearm were sprinkled with a papular eruption of a red and brownish colour, whilst the urine showed the existence of a large amount of albumen.

The case gradually became worse, and eight days after admission the man died. The temperature during the time he was in the hospital remained at 104° Fahr.; the pneumonia gradually increased in severity and extent; no diminution in the quantity of the albumen was apparent under treatment; and the weakness gradually became extreme.

At the *post mortem* examination the lungs showed a very manifest change, there being in both evidence of extensive pneumonia. In one lung there was 'a gangrenous cavern' in course of formation. On examination with the microscope, pus-globules were discovered in the pulmonary cells of both lungs. The kidneys showed the pathological appearances indicating extensive and acute Bright's disease. In the stomach there was a considerable amount of inflammatory action along the greater curvature. The other organs were healthy. On chemical examination, however, of the several viscera by M. Personne, no trace of the poison, the supposed cause of the illness and death, was discovered.

M. Raymond believes that it was an undoubted case of poisoning (chronic) by the action of an osmium compound; and he further promises to lay before the Société de Biologie, at which the original paper was read, the result of further experiments with osmium and its salts. We look forward with some interest to them. C. MEYMOTT TIDY, M.D.

HENSCHEL ON ACUTE ERGOT-POISONING.—Dr. Henschel reports a case in the *New York Medical Record* for September 1, 1874, where thirty minims of Squibb's fluid extract of ergot was given by mistake to an infant. Soon afterwards, there were severe abdominal pains, recurring every fifteen minutes and lasting hardly sixty seconds. There were slight tetanic contractions of muscles of face and extremities. Diarrhoea set in four hours after administration, and continued fourteen days. He believes that this case proves that it is the uterine contractions, and not the ergot, that destroys the fœtus during labour.

W. C. GRIGG, M.D.

REVIEWS.

On Poisoning by the Inhalation of Coal-Gas. By WILLIAM TAYLOR, M.D. Pp. 23. Edinburgh: Maclachlan and Stewart. London: R. Hardwicke, Piccadilly. 1874.

This interesting pamphlet has been reprinted from the *Edinburgh Medical Journal*, and contains the his-

tory of a Canadian, aged about fifty-five, who foolishly blew out the gas instead of turning it off, in his bedroom in one of the Edinburgh hotels. He was discovered quite comatose, but the efforts to revive him were so far successful that he lived for nearly two days. One special feature of the case was 'a steady, and almost incessant oscillation of the eyeballs.' The available cubic space of the room was 947 cubic feet; the proportion of gas could never have been more than about three per cent., or one in about 33½. Besides a very careful report of the symptoms in this case, there are notices of the Dundee and other cases, and an abstract of M. Tourdes' cases, referred to in the LONDON MEDICAL RECORD for August 5. There is no English translation of M. Tourdes' monogram, and therefore Dr. Taylor's work becomes additionally valuable. The Strasbourg gas appears to have contained 31 hydrogen, 22.5 of proto-carbonate of hydrogen, 6.0 of bicarbonate of hydrogen, 4.6 of carbonic acid, 14.0 of nitrogen, and 21.9 of carbonic oxide. Its mode of preparation was somewhat peculiar, especially in the large proportion of carbonic oxide, as Roscoe's analyses give about 7.8 as the percentage of 100 volumes of coal or cannel gas for illuminating purposes.

W. BATHURST WOODMAN, M.D.

MISCELLANY.

THE FLY-DIGESTING POWERS OF PINGUICULA AND DROSERA.—Mr. Andrew Murray writes to the *Gardener's Chronicle* that he has within the last few weeks made some observations at the Ochil Hills, Kinross-shire, on *Pinguicula* and *Drosera*, with reference to the fly-digesting powers which they are asserted to possess. He states that he found the leaves of the *Pinguicula* close, quite independently of the fact of a fly being in them or not. 'The leaves are found with their margins in all stages of curling over, some with no insect on them much more curled over than others with several.' The secretion which Dr. Hooker states to kill a captured insect he finds to be glutinous, and he believes that it does not fall on to the insect, but that death results from the secretion adhering to and closing up the spiracles by which the insect breathes. With regard to *Dionaea*, he suggests that it should be carefully noted (1) whether the secretion is never present until after an insect has been captured; (2) whether it is always present after one has.

RESPIRATION AND NUTRITION IN PLANTS.—Mr. Corenwinder has contributed to a recent meeting of the Société des Sciences, of Lille, an exhaustive series of observations on the processes of respiration and nutrition in plants. He supports M. Claude Bernard's view, that the process ordinarily known as the respiration of plants—the decomposition of the carbonic acid of the atmosphere—is really a process of digestion, and that simultaneously with this, plants carry on, by day as well as by night, a true process of respiration, similar in all respects to that performed by animals, consisting in an oxidation of the carbonaceous matters of their tissues. By a very careful series of analyses, performed mainly on the lilac and maple, M. Corenwinder determined that the proportion of nitrogenous matter in the leaves gradually and progressively diminishes from the time that they emerge from the bud till their fall; the proportion of carbonaceous matter increases very rapidly during April and May, and then remains nearly stationary till October; while that of incombustible substance increases during the whole period of vegetation. He distinguishes, therefore two periods in the vegetative season of the plant—the first period, when nitrogenous constituents predominate, is that during which respiration is the most active; the second, when the pro-

portion of carbonaceous substance is relatively larger, is the period when respiration is comparatively feeble, the carbonic acid evolved being again almost entirely taken up by the chlorophyll, decomposed, and the carbon fixed in the true process of digestion.

CREMATION.—At the Naturalists' Congress, lately held at Breslau, Dr. Reclam, of Leipzig, read a paper on 'Cremation,' on behalf of which he advanced many sanitary arguments. Dr. Reclam argued that the practice should be enforced in all cases of infectious disease as absolutely necessary to the public health. In ordinary cases he claimed only for every man the liberty of disposing of his remains after death as he might think fit. Then followed a minute description of a new burning apparatus, combining the highest efficiency with the greatest economy of outlay. A horse, for instance, could be thoroughly consumed in two hours with four shillings' worth of fuel. With the new system, the dead left upon the field of Gravelotte, men and horses together, might have been reduced to a harmless heap of white ashes in four days. In this case also, namely, after destructive battles, Dr. Reclam contended that cremation should be made obligatory. With liberty, however, as the general rule, he was persuaded that the reform will gradually work its way to universal acceptance. A trial was subsequently made of Dr. Reclam's new cremation apparatus, with the following result:—Half-an-hour after the corpse was placed in the furnace the soft parts of the body were thoroughly consumed, and in one hour the bones were reduced to a fine white ash.

DEMONIACAL POSSESSION.—An interesting work lately published by Dr. Legué of Paris, on the subject of the possessed nuns of Loudun, aptly illustrates the words uttered by Paracelsus, when, 300 years in advance of his time, he said, 'Yet before the world comes to an end, a great number of effects now supposed to be supernatural will be explained by strictly physical causes.' M. Legué shows, after studying and abstracting a number of curious documents relative to the unfortunate Ursulines of Loudun, that their confessions of demoniacal possession were simply due to peculiar forms of hysteria. The Abbess of Loudun, in particular, showed all the characteristics of the demonopathic epidemic, and whilst, according to her own account, under the sway of the devils Asmodeus and Balaam, showed the names of Mary and Joseph in bleeding letters on the back of the left hand. Another time she asserted that she was wounded at three points of the left side, whence demons issued from her body. This book contains fresh confirmation of that principle which maintains that pathology becomes changed with the flight of time. This principle, true in regard to all diseases, is especially so in relation to epidemic nervous disturbances, which borrow a portion of their characteristics from the state of contemporary manners and beliefs. A striking proof of this assertion may be found by comparing the story of the demoniac possession at Loudun with the last epidemic of the kind at Morzine, in which his Satanic Majesty is reported to have shown himself 'more reserved than he had ever previously been.' M. Legué's views are similar to those put forth by Hecker, in his work on the *Epidemics of the Middle Ages*.

THE Boston correspondent of the *Academy* records the death of Professor Jeffries Wyman, of Harvard College. He was born on August 11, 1814, and had consequently just completed his sixtieth year. He graduated at Harvard College in the year 1833; he then studied medicine in the Harvard College Medical School, and in Paris, carrying on his work in natural history at the Jardin des Plantes in that city. After his return to America he lived in Virginia, being Professor of Anatomy in the Hampton Sydney College of that State. In 1847 he accepted the post of Hersey Professor of Anatomy of Harvard College, and Professor of Comparative Anatomy in the Lawrence Scientific School, which positions he filled until his death, with great honour to the college and to himself. He was

also a member of the faculty of the Museum of Comparative Zoology. When George Peabody made his generous gift to the college for the establishment of the Museum of Ethnology, Professor Wyman was appointed Curator, and he had already made considerable collections for that Museum. He was a great worker, in spite of delicate health; but his reputation, except among those who kept up with his frequent and valuable contributions to scientific journals, was far behind his deserts. His articles may be found in the *American Journal of Science*, the *Smithsonian Contributions to Knowledge*, the *Boston Journal of Natural History*, and the *Proceedings of the Boston Society of Natural History*, of which society he was for many years president. He was the first to dissect the eyeless fish of the great cave in Kentucky; he discovered a parasite in the cerebellum of the snake-bird; he made several interesting discoveries about the aboriginal inhabitants of America; in short, he was unceasingly devoted to his studies. In Cambridge he had a certain number of pupils, who became deeply attached to him, but he was of too shrinking a disposition to have the large following that Agassiz had. His opinion on any scientific subject was of the utmost value, so careful was he not to make up his mind except after a thorough examination of every argument for and against. He has left behind him the deep impression of a man whose modesty and kindness were equal to his rare ability.

A SCIENTIFIC BEQUEST.—Lord Derby has announced in the *London Gazette* that the Italian Minister in London has communicated to him a copy of the will of the late M. Girolamo Ponti, of Milan, by which he has bequeathed a portion of his property to the 'Academies of Science of London, Paris, and Vienna.' It is understood that the relatives of the testator intend to dispute the will, and as it does not clearly appear what British society is indicated, the Secretary of State gives notice of the bequest, in order that those societies which may wish to put forward their claims, may take such steps in the matter as they shall think fit. The will, which is dated in January, 1856, contains the following passages. 'I dispose of the whole of what belongs to me on this day in favour of the three Academies of Sciences of London (capital of England), Paris (capital of France), and Vienna (capital of Austria), so that my said patrimony is to be divided among the said three academies in equal parts, for the purpose of founding with the produce thereof the institutions mentioned below, after deduction of the following charges: (600 lire for funeral expenses, and thirty lire yearly for masses, as well as all sums due from him, including his share of a provision for his mother, then alive). At the time of making the will, he stated his property, free of debts and charges, to amount to 865,000 Austrian lire (about 34,600*l.*) Each of the three academies above-named shall be bound to invest in a perfectly safe and profitable manner the third part of my patrimony which falls to its share, and with the proceeds to institute two annual competitions for ever, in equal amounts, so that together they may correspond to the total sum of the proceeds of the respective quotas, free from any expenses which may happen to be necessary for the institution of the said competitions. Consequently, each of the aforesaid academies will have to appoint a committee fit to decide upon the grant of the rewards annexed to the two competitions, which are to embrace the following branches:—1. Mechanics. 2. Agriculture. 3. Physics and Chemistry. 4. Travels by sea or by land. 5. Literature. The object of the committee must be to give the preference to whomsoever among the competitors that shall have advanced the sciences by the discovery of new and simple appliances, and this refers to mechanics, physics, chemistry, and agriculture; in regard to travels by sea and by land, whoever has distinguished himself by a long journey by land and by sea, or has been able to make propositions fitting to diminish the dangers inherent in the present systems, should have the preference; in default of inventors and distinguished travellers, the committee will turn its attention to the most distinguished publications of

original works, or at least of translations from other languages of works, upon the above-mentioned sciences and travels, including literature, that is, mechanics, agriculture, physics, chemistry, travels by land and by sea, and literature. Moreover, the decisions of the committee must be considered as final. The competitions, as I have said, are to be two in every year, and they are to begin one year after each of the above-mentioned academies shall have received its own third part according to the present disposition. Only natives of the country are to be admitted to the said competitions; therefore, only native English by the Academy of London, French by that of Paris, and Austrian Germans by that of Vienna. His personal effects, furniture, and books, he leaves to the Academy of Vienna, in order that as regards the effects and furniture, the proceeds of their sale may be added to the third part of his patrimony which falls to its share; and as to the books, that they may be added to its own library, or any other in Vienna which shall be chosen by it for public use.' In a subsequent addition, he says that 'in the above-mentioned dispositions all the increments are to be included which may have accrued from the fund of the property above-mentioned. Any other acquisition, whether from maternal inheritance or otherwise, and the proceeds thereof, shall be considered as disposed of as I now dispose of them, in favour of the Grand Hospital of Vienna, in order that they may be profitably employed, and in the most secure manner possible, in augmentation of its present endowment.'

WE have received from Messrs. Dunn & Hewett a sample of their new cocoa powder, unmixed with farina and sugar. Upon examination we find it to be a clear-flavoured perfectly pure cocoa of good quality, and prepared without any admixture. It has been introduced by the firm in question to meet the taste which has arisen for thin-drinking cocoas, and possesses the advantage of being of exceedingly moderate price.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17*s.* 4*d.*; free by post, 19*s.* 6*d.*

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2*s.* 6*d.* each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & CO., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The First Volume, containing upwards of Two Thousand Articles abstracted and compiled by a staff of Fifty Hospital Surgeons and Physicians, is now ready, price 19*s.* 6*d.* Cloth Cases for binding the Numbers for the year 1873 are also ready, price 1*s.* 6*d.* each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & CO.—Calcutta: THACKER, SPINK & CO.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & CO.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & CO., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, OCTOBER 7, 1874.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

A CASE OF LIGATURE OF THE COMMON ILIAC ARTERY: WITH REMARKS. BY DR. A. M. BARBOSA, OF LISBON.*

Ligature of the common iliac artery is one of the most formidable and difficult operations in surgery, and one of the most rare. In Lisbon, before I performed it in February 1873, it had been practised once only, twenty-eight years previously, by Professor J. P. Barral. My case, regarded especially from a clinical and anatomic-pathological point of view, was accompanied by circumstances of so great importance, that I have thought it right to give a history of it in this essay, which I had the honour of presenting to the first class of the Royal Academy of Sciences in Lisbon.

The paper is divided into six parts, viz.:

1. The history of ligature of the common iliac artery.
2. The condition of the patient before the operation.
3. The operative process employed, and the anatomy of the parts concerned.
4. The progress of the patient after the operation.
5. The necropsy.
6. Considerations arising out of the case and its results.

1. *History of Ligature of the Common Iliac Artery.*—The common iliac artery was tied for the first time in 1812 by Dr. William Gibson, of Philadelphia, to arrest hæmorrhage produced by a gunshot wound. The patient died thirteen days afterwards, from peritonitis and secondary hæmorrhage. Fifteen years later, ligature of the common iliac artery was performed by Mott, in a case of aneurism of the external iliac. In this case, the epigastric artery was wounded; but this did not interfere with success, as, in less than two months, the patient was completely cured, the ligature having been removed on the nineteenth day. This was the first time that the common iliac artery was tied for the cure of aneurism. Since that time, the operation has been performed more than forty times.

[Dr. Barbosa here gives an analysis of the thirty-two cases collected by Dr. Stephen Smith, of New York, in 1860, and referred to by Dr. Gross in his *System of Surgery* (1866), by Mr. Erichsen in his *Science and Art of Surgery* (1872), and by Dr. Le Fort in Malgaigne's *Manuel de Médecine Opératoire*, 8th ed. He refers also to nine others, mentioned by

Dr. Gross and Mr. Erichsen, making up the number to forty-one.]

Of these forty-one cases, thirty were fatal, and eleven ended in recovery. To these forty-one operations, I have to add four performed by Portuguese surgeons: one by Professor João Pedro Barral, of Lisbon, in 1845; one by Professor Antonio Bernardino de Almeida, of Oporto, in 1867; one by Dr. Antonio da Luz Pitta, of Madeira, in 1868; and one by myself in 1873.

My honoured master and friend, J. P. Barral, professor in the Medico-Chirurgical school of Lisbon, performed the operation in the St. Miguel ward in the hospital of St. José, in 1845, on a man aged about fifty-five, on account of an aneurism of the left femoral artery which was supposed during life to implicate also the external iliac. The operation was commenced, and should have been completed, by the surgeon of the ward, Dr. J. F. de Sousa Gomes; but, being prevented from continuing, he asked Dr. Barral, who was present as a spectator, to finish it. The peritoneum was wounded; and, in consequence of an unusual relation of the ureter to the common iliac, it was included in the ligature. The patient died the next day. My colleague, Dr. A. B. Ribeiro Vianna, who was present at the operation and gave me this history, possesses the pathological specimen, and has been good enough to entrust it to my care. It will be seen that the aneurism, although during the patient's life it appeared to be situated in the external iliac artery, was altogether femoral, occupying the portion between the origin of the epigastric and circumflex arteries, which must have been permeable, and the division of the common femoral artery into superficial and deep. The whole of the external iliac artery, nearly an inch and a half long, was intact, and might have been tied nearly an inch from the internal iliac. The aneurismal sac, which is now about as large as a moderate-sized lemon, extended three centimètres (nearly half an inch) upwards over the external iliac, and two and a half centimètres downwards on the superficial femoral artery. The ureter was included in the ligature with the common iliac artery, which was tied just above its division.

Ligature of the vessel was performed by Dr. A. B. de Almeida on May 6, 1867, in the hospital of St. Antonio, in Oporto, in the case of a woman, aged sixty, who had an aneurism of the gluteal artery. The ligature came away on June 2, twenty-six days after the operation, and the aneurismal tumour was reduced to a very small size. The patient, however, who at the termination of the session had been removed from the clinical to the general ward, died on July 16, seventy days after the operation, with symptoms of purulent infection, according to the information which the operator has been kind enough to communicate to me.*

The late Dr. A. da Luz Pitta, director of the medico-chirurgical school in Madeira, performed ligature of the left common iliac artery, in the hospital of Santa Isabel, at Funchal, on January 16, 1868, in a case of aneurism of the upper third of the femoral and lower half of the external iliac in a man aged thirty-nine. The process employed by Dr.

* Memoria sobre a laqueação da arteria iliaca primitiva, a proposito d'esta operação praticado em 7 de Fevereiro de 1873 no hospital de S. José de Lisboa, e apresentada á Academia Real das Sciencias de Lisboa por Antonio Maria Barbosa. *Gazeta Medica de Lisboa*, nos. 12, 13, 14, 15, 16, and 17, 1874.

* A thesis on this case was presented to the medico-chirurgical school of Oporto by Senhor João Pereira de Albuquerque, now my colleague; it is deposited in the library of that school. The *Escholaste Medico* of November 15, 1867, alludes to the same case in a letter from the late army surgeon, A. Gomes do Valle.

Pitta was nearly the same as that adopted by Astley Cooper in his celebrated case of ligature of the aorta, in 1817, for aneurism of the external iliac; and by Garvizo for the ligature of the common iliac in two cases, one of which was successful. The operator made on the left side of the linea alba, at the distance of about 0·3 inch, an incision about 1½ inches long, commencing half an inch above the umbilicus, and carried in a nearly straight direction downwards and outwards. The tissues were divided down to the peritoneum, which was largely opened; the surgeon then introduced his hand into the abdominal cavity, thrust aside the intestines, which partly escaped through the lips of the wound, divided the peritoneum again posteriorly, isolated the artery, and tied it. The patient died of peritonitis thirty hours after the operation. The necropsy revealed the signs of intense general peritonitis, and showed that the aneurism extended from the upper third of the femoral to nearly an inch below the bifurcation of the common iliac, which was tied not more than one-third of an inch from its origin.

The other operation practised in this country was one which I performed on February 7, 1873, on a man sixty-two years old, who had an aneurism arising from the left femoral artery, and extending over the external iliac in such a way as to lead to the supposition during life that this vessel was also extensively implicated in the aneurismal dilatation. The patient died of septicæmia on the 14th, seven days after the operation.

The number of known cases of ligature of the common iliac artery thus amounts to forty-five. Of these, thirty-three were fatal and twelve successful. The case of Dr. Almeida must be placed among the latter, although the patient died seventy days after the operation; for the ligature had been detached, the aneurismal swelling was much reduced, and the patient could but die in the hospital of St. Antonio, the unhealthy conditions of which no one who has not seen it can imagine to be as great as they really are. In eleven cases, the peritoneum was wounded, and death followed in ten. The operation was performed in thirteen cases to restrain hæmorrhage, and was successful in one. In most of the cases—twenty-five—the operation was performed for the cure of aneurism—of the external iliac and femoral in twenty-three cases, and of the gluteal in two: nine of these cases were successful, and sixteen fatal.

2. *Condition of the patient before the operation.*—Theodoro Luiz dos Santos, aged sixty-two, married, a carpenter, residing in Lisbon, was admitted into the Santo Antonio ward of the hospital of S. José on January 17, 1873, with an extensive tumour occupying the left inguinal region, and extending as high as the upper part of the internal iliac fossa of that side. It had first appeared about ten weeks previously. The patient had always enjoyed good health; he had never had rheumatism, nor had he been addicted to the use of alcoholic liquors. He had been, however, for many years subject to an obstinate cough, which was relieved by the use of cigars. During a very severe attack of cough in the beginning of November, 1872, he suddenly perceived a slight painful sensation in the middle of the left crural arch. He still walked about and followed his trade as a carpenter. On placing his hand on the part where the sensation referred to was felt, he found that it was more raised than the corresponding part on the other side; and that there was unusual and very distinct pulsation. He continued at his ordinary work without any

treatment until, eighteen days later, when he was assisting to raise some rather heavy masses of wood, he felt severe pain in the left groin, the part increased in bulk, and the pulsations became continuous and more intense.

For two days after this aggravation of the symptoms he was in much greater distress; he could not walk, and there was swelling of the foot and lower part of the leg. He remained confined to his room at home, and for about two months treated himself by means of fomentations and poultices. He gradually, however, became worse; the pain in the groin became much more severe, and extended upwards to the iliac fossa and downwards to the knee. The whole limb became swollen, especially after standing erect and walking.

In this condition he was seen by my colleague, Senhor J. Q. de Avillar, who recognised the existence of an aneurism, apparently of the external iliac, and advised him to enter the S. José Hospital. When I saw him on January 18, his condition was as follows.

The patient lay on his back, with the trunk raised, forming a very obtuse angle with the thighs. Any other position, he said, produced cough, and pain in the region of the swelling. He was of lymphatic temperament, with an aspect indicating debility and great suffering. His skin was pale; the abdomen was large, from a great quantity of subcutaneous fat. The whole left lower limb was hard and cedematous. The swelling of the thigh extended to the upper part of the iliac fossa, effacing the fold of the groin. On palpation a large tumour was felt, occupying the whole iliac fossa, and reaching as far as the upper and inner part of the thigh, where it became confounded with the cedema, which prevented its limits from being distinctly ascertained. From the crural arch to the upper limit, it measured eighteen centimètres (two and three-quarter inches). Its volume was nearly equal throughout, as far as could be ascertained by palpation through the thick abdominal walls and the cedematous integuments. It appeared, however, to be largest just above the crural arch, where its transverse extent was nine centimètres. The swelling was pulsatile in a great part of its extent. The maximum intensity of pulsation was at and above the crural arch, over an area of six centimètres (nearly an inch) in diameter. From this point, towards the limits of the tumour, the pulsation became weaker. In the part where the pulsation was most distinct, an expansive movement coinciding with the arterial diastole was distinctly perceptible, that is, at the middle of Poupart's ligament; it ceased to be perceived six centimètres above and below this part. At the same points where these signs were obvious on palpation, the stethoscope detected a rough intermittent bruit, synchronous with the pulse, and most intense, like the pulsation and expansive movement, at the middle of the crural arch. The tumour was elastic, without remarkable hardness or resistance, and but slightly tender on pressure; the patient, however, felt in the groin and in the neighbourhood a dull pain, which became aggravated at irregular intervals, and extended down the inner side of the thigh to the knee and sometimes to the foot. Nothing was perceived, on careful percussion and auscultation, in the heart and large vessels; there was no increase of size nor alteration of rhythm in the pulsations; neither was there the least abnormal murmur indicative of lesion of the heart or vessels. Auscultation over the lungs

and bronchi detected some rough and sibilant râles on both sides of the chest, the result of mild chronic bronchitis which the patient had had many years, and which accounted for the dry cough by which he was more or less troubled. The pulse was regular, weak and soft, 80. The temperature in the left axilla was 37.8° C. (100° F.) The remaining functions were performed regularly.

In the presence of those symptoms and signs, I diagnosed spontaneous aneurism of the lower part of the left external iliac artery, close above Poupart's ligament. I also believed that the aneurism, at first limited, had become converted, in consequence of the movements and the imprudent exertions of the patient, into a circumscribed false aneurism; and that this explained the characters of the tumour. Under these circumstances, no other treatment was indicated than that which would have the effect of interrupting the circulation in the aneurism, by ligation of the external iliac, if this vessel could be tied five or at least three centimètres from its origin, or of the common iliac above its division. Notwithstanding that it was not impossible that in these circumstances the external iliac might be tied, yet, considering the age of the patient and the manner in which the aneurism had formed and developed, I thought that in all probability I should have to tie the common iliac—which was indeed the case.

Until an operation should be determined on, I applied a compress over the groin and bandaged the whole limb; and prescribed some pills to allay the cough, and a tonic but not stimulating diet.

My colleagues in the school and hospital being consulted with regard to the proposed operation, agreed that it was the only means that could save the patient; at the same time, they recognised its difficulties and dangers, in view of the size and extent of the tumour and of the probably atheromatous state of the arteries.

Unforeseen circumstances interfered with my attendance at the hospital for some days. The operation was therefore deferred till February 7, on which day I performed it in the operating theatre of the medico-chirurgical school, in the presence of the pupils and of my colleagues, and of a large number of members of the profession in Lisbon.

(To be continued.)

LUNIER AND OTHERS ON THE PRESENCE OF FOREIGN BODIES IN THE DIGESTIVE PASSAGES.

At a recent meeting of the Société de Médecine of Paris, reported in the *Gazette des Hôpitaux* of Sept. 15, some curious records of cases of foreign bodies in the digestive passages were related.

M. Lunier cited the case of a young woman, a maniac, who had several times tried to commit suicide. On the first occasion she took a decoction of two or three packets of tobacco, which she had boiled for half an hour. Another time she swallowed two quarters of a hundred of pins, and buried another quarter of a hundred in her scalp. Finally she procured two hectogrammes (nearly half a pound) of gunpowder, set fire to it, and placed herself over it. However, none of these attempts resulted in anything but making her ill. She passed a great number of pins *per anum*, and it was only at the end of two or three months those in the scalp were discovered, and thirty of them removed. At the end of

three months she was completely cured. This fact tends to confirm the relative immunity from suffering which is peculiar to the insane.

M. Péter related that whilst he was house-surgeon at the Hôpital de la Charité, a young man came under his care suffering from an abscess in the right groin. The abscess was peculiar in appearance, its edges were horny, and the pus which issued from it was foetid and contained faecal matter. M. Giraldès introduced a sound into the abscess, and at the bottom of it felt a hard body which emitted a metallic sound. It was then clear that the abscess was caused by the presence of a foreign body, of which the extraction was difficult in consequence of the indurated faecal matter which enclosed it. This foreign body was found to be a pin which had perforated the cæcum, and had been stopped in further migration by the head. Peritonitis came on, and the patient died.

In consequence of this incident, M. Péter wrote a work on the migration of foreign bodies in the digestive passages, for which he collected a certain number of cases. Some of them are as follows.

A juggler having swallowed a sabre, was brought into the Charité Hospital. Serious consequences followed. Adhesive inflammation ensued, resulting in an abscess. The sabre became divided into two parts; and the extraction was performed in two operations.

A sailor, for half a pint of brandy, swallowed a knife, which he afterwards passed easily. But one day the knife would not pass, serious accidents came on, and caused his death in three days. The necropsy revealed chronic ulcerous gastritis. The knife was found, but the horn handle had been completely digested, and there only remained vestiges of the five or six blades it had contained.

Another case was that of an hysterical woman, who had swallowed a packet of needles, of which 396 issued from her breasts, arms, chest, etc.

M. Réliquet related a case of strangulated hernia, operated on by M. Maisonneuve, in which it was ascertained during the operation that all the effects of strangulation had been brought on by the presence of a lark's claw, which had been swallowed by the patient and had lodged across the intestine.

M. Forget drew attention to the preparations presented by M. Gallard's house-surgeon, from the body of a waiter, who, having entered the hospital on one occasion in consequence of having received some blows on the chest, which brought on some general symptoms; left cured. Soon after, however, he again came into the hospital for an abdominal affection, to which he succumbed. At the necropsy, old adhesions between the pericardium and the corresponding wall of the lung were found. These two organs were held together by a pin, of which the point issued into the interior of the pericardium, where it was perfectly free. It but rarely touched the heart, on the surface of which was found a series of concentric curves produced by the point of the pin, which inscribed the heart's movements on itself, just as the stilet of a sphygmograph would have done. This case, besides being very interesting from a physiological point of view, proves that the swallowing of a single pin will sometimes cause death.

M. Durozier said that coins seemed to find easy passage through the digestive tube. Thus, a man, who came into the Hôtel-Dieu, after having swallowed six twenty-franc pieces, passed them all, and recovered without any bad symptoms.

BOURNEVILLE ON THE THERAPEUTIC AND PHYSIOLOGICAL PROPERTIES OF BROMIDE OF CAMPHOR.

Bromide of camphor, or, to use the nomenclature of MM. Maisch and W. A. Hammond, monobromide of camphor (*camphre monobromé* of M. Wurtz) is a substance in which an equivalent of the hydrogen of camphor is replaced by an equivalent of bromine. This new combination is thus very rich in bromine, since it contains of this element more than a third of its whole weight. It is a perfectly definite substance, and, when well prepared and pure, it is white, of velvety appearance, and crystallises in elongated prisms, which are sometimes of a good size. These prismatic needles are often united at their bases, and thus form thick tufts of great beauty. The odour of the bromide of camphor is rather penetrating, and resembles that of camphor and mouldy wood in conjunction.

The first researches on the physiological action of bromide of camphor were made by Dr. Bourneville, and were communicated by him to the Société de Biologie on June 13. This investigator experimented on guinea-pigs, rabbits, and cats. The results of his experiments induced him to assign the following physiological properties to this new drug. Bromide of camphor lessens the number of the pulsations of the heart, and determines a contraction of the auricular vessels in guinea-pigs and cats; it diminishes the number of inspirations, and lowers the temperature in a regular manner. When the bromine is given in a poisonous dose, this diminution of temperature becomes more and more marked, until death ensues. In the cases which recover, the diminution of temperature is succeeded by an increase, which continues until the initial figure is reached. The rise of the temperature, however, occupies longer time than its fall. Bromide of camphor has inconceivable hypnotic properties, and appears to act chiefly on the cerebral system. The nervous system appears not to accommodate itself to the influence of this drug, since a prolonged use of it, in the case of cats and guinea-pigs, caused emaciation.

Starting from these physiological conclusions, the results of his experiments, M. Bourneville deduces from them the therapeutic properties of bromide of camphor. He considers that the use of this agent is indicated whenever it is necessary to produce decided calming of the circulation, and especially for the cerebro-spinal nervous system. The antispasmodic properties of bromide of camphor are, in M. Bourneville's opinion, clearly proved. M. Deneffe, of Ghent, is, we believe, the first person who employed bromide of camphor as a therapeutic agent. He found it of great service in the case of a man aged thirty, who was suffering from delirium tremens, accompanied by tremblings, excitability, insomnia, and visual delusions. The patient improved rapidly, and a thorough recovery followed, unattended by relapse.

Dr. W. A. Hammond, of New York, employed bromide of camphor prepared by M. Maisch, Professor at the College of Pharmacy in Philadelphia, in the form of beautiful free crystals slightly tinted with yellow. Dr. Hammond mentions instances where the convulsions of children; attacks of inveterate hysteria, lasting from five to twelve days, and headache, consequent on mental excitement or excessive study, were cured by the use of this drug.

Dr. Bourneville made his therapeutical experiment

at the Salpêtrière, under the direction of M. Charcot. The form of the drug administered was the same as that which has been employed up to the present time in all the hospitals of Paris—Dr. Clin's bromide of camphor dragées. In addition to the physical properties of bromide of camphor already mentioned, its characteristic odour and disagreeable flavour, it may be noted that it is insoluble in water, and changes when exposed to the air, so that the dragées are the best form in which to administer it. Each dragée contains exactly ten centigrammes ($1\frac{1}{2}$ grain) of the bromide of camphor, covered by a thin coat of sugar, which preserves the drug, masks both its odour and flavour, and renders it easy of deglutition. These dragées become rapidly disintegrated in the stomach. Among the cases already published we find the following.

In one case, a woman aged sixty-two, suffering from heart-disease attended by insomnia, twenty centigrammes only (two dragées) were efficacious. In the case of a woman aged forty-six, who was suffering from progressive locomotor ataxy, in whom insomnia alternated with disturbed sleep troubled by nightmares, it was necessary in order to obtain a decided improvement to administer eighty centigrammes (eight dragées). A woman aged forty-six, who for six years suffered from chorea, who had not been able to walk for a year, and was tormented by such incessant and violent movements that they drew her out of her bed, and who was also unable to sleep, had administered to her as high a quantity as 120 centigrammes (twelve dragées). Her sleep became calmer, she remained quietly in her bed, could walk a little, and often remained fifteen or twenty minutes undisturbed by choreic movements.

Three women under the care of M. Charcot, of the respective ages of fifty, sixty, and sixty-seven, were attacked by paralysis agitans, and pronounced incurable. They took from twenty centigrammes to one gramme (three to fifteen grains) of the bromide of camphor, daily, in quantities varying from one to ten dragées, in progressive doses. A marked amendment followed.

Bourneville (*Progrès Médical*) has submitted the efficacy of bromide of camphor to a severe test by choosing as a field for his experiments a hospital for incurables. If it succeeded in these obstinate cases, still greater was the probability that it would act beneficially where the conditions were more favourable, and the illnesses of more recent origin. A patient in the Hospital de la Pitié, twenty-four years of age, suffering from acute rheumatism, was attacked by chorea in the left arm. He was cured in five days. The dose was sixty centigrammes (nine grains) daily, given in six dragées.

In the same hospital, a woman, aged twenty-two, was attacked by violent hysterical chorea, with hysterical vomiting. The dose given was first forty, and then sixty centigrammes, daily. Her cure was rapid.

A young woman, a patient in the Necker Hospital, suffering from induration, with insufficiency of the mitral valve, showed symptoms of poisoning from the first day digitaline was administered to her. The digitaline was discontinued, and the bromide of camphor substituted. The heart-beats diminished in frequency and became regular. The medicine was relinquished, and the improvement obtained continued the same a fortnight later.

A man in the same hospital, presenting the same conditions, received equal relief.

A young woman, suffering from nocturnal incontinence of urine, had taken bromide of potassium during fifteen days without any amendment. Four dragées of the bromide of camphor cured this painful infirmity, at least for the time being. The patient is still under treatment.

A patient who was tormented by nervous cough, which entirely deprived her of sleep, took two dragées, night and morning, and the symptoms were abated in a few days.

At the Cochin Hospital a case of paralysis agitans was considerably calmed by a daily dose of four dragées. The patient was a woman, about forty years of age.

At the present time our knowledge of the physiological action of the bromide of camphor, and of its value as a therapeutic agent, is imperfect. It is, nevertheless, evident that the administration of this drug has been followed by incontestably beneficial results, which have been corroborated by observation in a number of the hospital wards. Bromide of camphor is a well-defined substance, having a characteristic crystallisation, smell and flavour; and a powerful sedative both to the nervous system and circulation, acting as a hypnotic and regulating innervation.

It would be premature to specify the precise dose which ought to be administered. In the generality of ordinary cases it has been given to adults in doses of from twenty centigrammes to one gramme, a dose two or three times during the morning, a dose before dinner or with it, and, finally, another before going to bed. The dose naturally varies according to the illness and the special symptoms presented.

E. LAWSON.

ANATOMY AND PHYSIOLOGY.

TILLMANN'S ON THE HISTOLOGY OF THE JOINTS. H. Tillmanns (*Archiv für microscopische Anatomie*, 1874, vol. x.) has investigated the synovial membranes and villi of the joints, and finds in opposition to Hüter (*Virchow's Archiv*, vol. xxxvi.) Böhm (*Inaug. Diss.*, 1868, Würzburg) and in unison with Schweigger-Seidel (*Ludwig's Arbeiten*, 1866) that in man, dog, rabbit, and pigs there exists on the inner surface of the synovial membrane a continuous epithelial layer, which can be isolated, by careful scraping with the knife, from its fibrillar base. The nuclei of the epithelial membrane lie sometimes grouped together, sometimes widely apart from each other. At many places, the epithelium consists of several layers. The individual cells of the epithelial membrane can be isolated, and this is best done by placing for several days the joints of freshly killed animals (dogs, rabbits) or those of man as fresh as possible in a solution containing one-third per cent. of bichromate of potash. Under the epithelial membrane lies a very rich capillary network. The assertion of Hüter, that the blood-vessels lie naked on the inner surface of the synovial membrane between the cellular elements, is thus shown to be incorrect. The epithelial layer of the synovial membrane is not formed quite like the epithelium of the other serous membranes. In consequence of the friction during the movements of the joint it is exposed to injuries, and is liable to a kind of inflammation. Several layers of epithelium are to be observed, of which the uppermost layer is often

slimy and fattily metamorphosed; here and there the epithelial membrane is wanting, so that holes are present in it. On account of the changing situation, and the above-described peculiarities of the inner layer of the synovial membrane, the author thinks that the method of treatment by silver, however valuable this method may be for other situations in the body, is unfavourable for investigating the structure of this membrane. The author criticises the results obtained by this method in relation to the inner synovial layer, and regards them as artificial products, as precipitates of the silver in the synovia.

The epithelial layer of the synovial membrane passes also to the intra-articular ligaments, *e.g.* the round ligaments, the ligamenta cruciata of the knee-joint, and covers them completely; whilst the inter-articular ligaments, *e.g.* of the knee-joint, are only covered on those places which are free from pressure, *i.e.* on the margins. The articular cartilage is devoid of epithelium, both in the adult and in the foetal condition of man and the mammalia. Tillmanns found, in opposition to Reichert, no complete epithelial covering of the cartilage. He could only find a more or less extensive extension of the epithelium on the cartilage, and this corresponded to the frequency of the excursion in the movement of the different joints.

On the inner surface of the tendon of the quadriceps muscle, the epithelial membrane was frequently found to be penetrated; sometimes the most beautiful epithelium was found, sometimes holes, and sometimes only isolated cells, which, partly with their thick hyaline capsule, gave the impression of cartilage-cells, and which were not to be distinguished from actual cartilage-cells. In one case, on the inner surface of the quadriceps, a peculiar flat epithelial-like cellular membrane, which could be raised up in folds from its base, was found. Downwards towards the patella this membrane passed into the ordinary epithelium, while upwards it shaded off into isolated cells, many of which could not be distinguished from cartilage-cells. Cellular structures were also found in the tissue of the tendon of the quadriceps, which partly were not to be distinguished from ordinary cartilage-cells, and partly resembled those 'elastic cell-plates' described by Boll in the tendon of the frog. (Compare Kölliker, Lehmann, Ponfick, Bruce, and V. Török.) These cells lay partly several together in the fibrillar tissue, and partly on the bundles of connective tissue. It is very probable that these cells have become changed from the endothelium.

The synovial villi of man, the dog, rabbit, and pig were also investigated. Tillmanns distinguishes true and false villi. The true synovial villi have always an epithelial covering, which can be isolated by continued shaking of it. The single epithelial cells were also here isolated, and show the same peculiarities as those of the synovial membrane. According to the nature of the ground-substance, several kinds of true villi can be distinguished; 1. Mucous villi, without a fibrillar basis; 2. Fibrillar villi; 3. Fat villi; and in the middle of numerous mucous villi a fibrillar basis capable of being isolated is to be found; 4. Muco-fibrous villi, which are surrounded by mucilaginous inter-fibrillar connective tissue. In the origin of 'daughter-villi' the proliferation of the epithelial membrane plays a very important part. At first, on the margins of the 'mother-villus' epithelial buds of different sizes appear, which gradually

increase to 'daughter-villi,' and derive their ground-substance more or less from the 'mother-villi.'

The false villi are derivatives of the hyaline cartilage, which splits up, even in quite sound joints, into fine villous threads; they are always devoid of vessels and without epithelium. Only those villi originating from the cartilage have partly vessels and partly epithelium, which split off at the boundaries of the epithelial covering and vascular loops, and raise the epithelium and vessels with them at the same time. These false villi occur very often. In and upon the fibrous ground-substances of the false villi cartilage-cells are always to be distinguished. By the action of a medium strong solution of permanganate of potash, changed four or five times daily, or of a ten per cent. solution of chloride of sodium, the hyaline ground-mass of the cartilage in freshly killed dogs and rabbits splits up into individual cartilage fibres. From this it is probable that the apparently homogeneous ground-substance of hyaline cartilage may be made up of single cartilage-fibres, which are glued and held together by some substance soluble in permanganate of potash. Between these cartilage fibres lie the cartilage-cells, which have no processes.

With reference to the mucin of the synovia, the author believes that the often-observed muco-fatty solution of the epithelium and the large quantity of mucus in the villi play an important part.

WILLIAM STIRLING, D.Sc., M.B.

GOBLEY ON CHEMICAL RESEARCHES ON THE BRAIN.—The conclusions at which M. Gobley arrives (*Journal de Pharmacie et de Chimie*, Sept.) are as follows.

1. The cerebral substance of man contains about eighty per cent. of water.

2. It contains two albuminoid matters; the one soluble in water, and not differing from albumen; the other insoluble, and for which he has proposed the name of *cephaline*.

3. The fatty matter of the brain is formed principally of cholesterine, of lecithine, and of cerebrine; and it contains, besides, traces of oleine and of margarine.

4. The brain contains the ordinary salts of the system, and extractive matters, some of which are soluble in water and in alcohol, others soluble in water and insoluble in alcohol.

5. During putrefaction, the cerebral pulp furnishes acid products, among which are found oleic, margaric, phosphoglyceric, and phosphoric acids.

6. The composition of the brain may be considered as represented, on an average, for 100 parts, by:—

| | |
|--|--------|
| Water | 80.00 |
| Albumen | 1.00 |
| Cephaline | 7.00 |
| Cholesterine | 1.00 |
| Cerebrine | 3.00 |
| Lecithine | 5.50 |
| Oleine and margarine | .. |
| Inosite, creatine, xanthine, etc. | .. |
| Aqueous and alcoholic extractive matters | 1.50 |
| Chlorides of potassium and of sodium, phosphates of potash, of lime, and of magnesia, etc. | 1.00 |
| | 100.00 |

ALEX. B. MACDOWALL.

STONE ON THE INFLUENCE OF WIND-INSTRUMENTS UPON THE LUNGS.—To the number of the *Philosophical Magazine* for August, Dr. Stone

contributes a short paper 'On Wind-Pressure in the Human Lungs during performance on Wind-Instruments.' It has been stated by several writers, and has hitherto been accepted as true, that the forced expiration employed in playing upon wind-instruments tended to produce emphysema of the lungs. As, however, such pressure had never been accurately measured, Dr. Stone has carefully investigated the subject. Two modes of experiment were employed.

1. On measuring by means of a water-gauge the extreme pressure which could be supported by the muscles of the lips both in trained musicians and in persons unaccustomed to the use of wind-instruments, the difference of variation was very great. It was found that when the lips were supported by a capped mouth-piece, similar to that employed in brass instruments, a greater length of the column of fluid in the gauge could be supported. The lip-muscles invariably gave way long before the expiratory power of the thoracic muscles was exhausted. It was found that the majority of untrained persons could not support more than four or five feet of water.

2. After a small gauge had been inserted into the mouth at one of its angles, various wind-instruments were tried, trained performers only being used for purposes of experiment, and the pressure exerted being only just efficient for the production of 'an average orchestral tone.' The greatest difference between the highest and lowest note was found in the clarinet, these requiring fifteen and eight inches of pressure respectively. It was noted that the force required was in general small, not exceeding or, indeed, attaining the pressure of a fit of sneezing or of coughing, and it was therefore concluded that wind-instruments are 'very unlikely to injure the lungs, or to produce the emphysema erroneously attributed to them.'

J. C. GALTON.

GALIPPE ON THE ACTION OF CANTHARIDES ON THE PUPILS.—*Le Progrès Médical* of July 13, 1874, states that M. Galippe has found dilatation of the pupils in all cases in which he has examined them, after the application of a blister.

MEDICINE.

MORTON ON TRANSFUSION OF BLOOD.—Dr. Thomas G. Morton, of Philadelphia, has published, in the *American Journal of the Medical Sciences*, July, 1874, a paper on 'Transfusion of Blood,' with a report of eight cases and a description of a convenient apparatus for performing the 'mediate method.' The paper commences with the pretty usual, and perhaps pardonable, flourish about the transcendent powers of transfusion—pardonable, because to achieve success in any direction is a legitimate ground for being somewhat enthusiastic about the means employed. Dr. Morton says, 'Transfusion of blood may be so readily performed, and with such entire safety, that it is somewhat surprising that this recognised life-saving operation has not been resorted to more frequently.' The details of three cases are given in full. The first was a case of lacerated wound of the face, occurring in a young man of hæmorrhagic diathesis. All the means used—including tying the common carotid—failed to arrest the bleeding, until at length he appeared to be in a comatose condition, and dying. On October 20,

1869, eleven ounces of defibrinated blood were transfused. A marked rigor followed the operation. In two hours the patient was semi-conscious. On October 21, the lips had a better colour, and the patient was perfectly rational, able to sit up, bleeding ceased. On the 26th he was walking about the ward, and was presented to the medical class. He continued to improve till November 3, when the internal jugular vein gave way, causing death on the 5th. The operation prolonged life over two weeks. The second case was one of carcinoma of the stomach, with leucocythæmia and great prostration. The patient, Mr. C. K., aged forty-five, was greatly blanched from mal-assimilation of food, and speedy death seemed inevitable. On November 12, 1870, about six ounces of defibrinated blood was injected into the median basilic vein of the left arm. No unpleasant symptom was observed, either in the respiration or circulation, during or after the operation. The gums and lips of the patient, which had had a blanched appearance, assumed a decided tint, which gradually deepened; the strength and spirits revived, and in all respects a great improvement was observed. Two months afterwards the health again rapidly failed, with constant sickness, and death occurred March 23, 1871. In this case (Dr. Morton says) transfusion gave temporarily a new lease of life. The third case was one of purpura hæmorrhagica, with nasal and alveolar hæmorrhage. Ida H., aged eleven, after a long previous illness, on February 7 and 8, 1874, was almost bloodless, and death seemed imminent. Transfusion being agreed to, the median cephalic vein in the left arm of the child was opened after much difficulty, on account of the small size and collapsed condition of the vessel. Two ounces of blood were injected. No unpleasant symptoms supervened. The pulse, which before was imperceptible, could now be counted. The patient began to take more food, was able to move about, and progressed favourably until March 29, when serious hæmorrhage came on from the falling out of a tooth. The next day, purpuric spots reappeared, and she became again very prostrate. Transfusion was at once performed. Six ounces of defibrinated blood were injected with immediate good effect. There having been a difficulty with the vein in the arm on the previous occasion, the saphena vein of the right leg, just above the ankle, was selected. On April 7 she was doing well, was up and about as usual, had excellent pulse, and no appearance of having lately suffered the loss of so much blood. On May 26 she was in perfect health.

Dr. Morton gives short notes of five other cases sent to him by Dr. J. G. Allen. Three of these cases were successful. One patient lived eighteen months after the operation, and then died from hæmorrhage after a miscarriage. Of one case Dr. Allen says: 'You will remember we accidentally' (Dr. Morton was present at this case) 'passed into the vein two or three little bubbles of air not larger than a pea—a kind of froth which had collected upon the blood in the syringe; this was followed by, and the probable cause of, the fit of gasping and threatened syncope which lasted about half a minute, and which at the time was attributed to want of air from many persons crowding over the bed.' This patient made a good recovery. In all the cases human blood was employed. The instrument used by Dr. Morton is simply a slight modification of an ordinary glass syringe—to hold about two ounces. In one of the cases, he speaks of filling the syringe several times. [Would it not be

better to use a larger syringe, like Dr. Braxton Hicks', to hold four to six ounces?—*Rep.*] The vessel for receiving the blood contains a chamber for warm water (on Higginson's principle) for keeping up its temperature, which is shown by a thermometer placed outside.

[Dr. Morton's is a good practical paper, and the cases well illustrate the advantages that may be expected in certain conditions from employing the 'mediate form of transfusion with defibrinated blood.' Of course there are many points in the paper open to discussion, but the facts are most valuable.—*Rep.*] H. M. MADGE, M.D.

VILLEMIN ON THE CAUSES AND NATURE OF SCURVY.—M. Villemin (*Bulletin de l'Académie de Médecine*, no. 32, 1874) has recently published a communication on scurvy, in which are contained some novel views as to the causes and nature of this affection. These views, like those of MM. Levin, Legroux, and Laboulbène, are based upon observations of the severe epidemic of scurvy which occurred in Paris during the military operations of 1870–71. M. Villemin has also brought to bear on this subject an extensive acquaintance with and the results of a careful comparative study of the many elaborate reports concerning previous epidemics of scurvy in different countries. He holds that most of the views held concerning the etiology and essence of the affection cannot stand the test of a strict critical examination, based on the study and comparison of various observed epidemics. He discusses the various supposed causes of scurvy, such as mental depression, abuse of tobacco, fatigue, cold, humidity, defective alimentation, saline agents, etc., and states that the affection is not determined by any of the numerous causes assigned to it in classical works on its etiology, and that the inductions drawn from one epidemic have been opposed by observation of another epidemic. Many facts, gathered from the published records of epidemics, both of land and sea scurvy, are given to show that a reduced supply, and even absolute deprivation, of fresh vegetables cannot alone give rise to scorbutic symptoms. M. Villemin next discusses and opposes the views of Dr. Garrod, who bases his opinion as to deficiency of potash-salts in food as a cause of scurvy, upon the propositions that potash exists in much diminished quantity in the food of scorbutic subjects, that antiscorbutic remedies contain a considerable proportion of potash, that the potash of the blood and urine is reduced in quantity or altogether absent, that the subjects of scurvy recover on the addition of potash to their food without the use of fresh vegetables and succulent fruits, and lastly, that the theory which attributes scurvy to a deficiency of potash explains satisfactorily most of the symptoms of the affection. According to Dr. Garrod's own tables, it is shown that potash does not exist in smaller quantities in the food consumed by scorbutic than that used by non-scorbutic persons. Antiscorbutic remedies contain, it is true, a large proportion of potash, but, as M. Villemin points out, these are always taken in very small quantities, and supply very little of this salt to the economy. One does not consume oranges and lemons as one consumes bread, meat, and legumes. Half an ounce of lime-juice does not contain more than half a grain of potash, which is a smaller quantity than is contained in one ounce of salted meat or dry peas. The deficiency of potash in the blood and

secretions is regarded by M. Villemin as an effect, and not as the cause, of scurvy. In any specimen of blood the quantity of potash is in direct proportion to the quantity of blood-corpuscles. Agglobulism is a very marked symptom of scurvy, and generally precedes every other manifestation of the affection. When an individual becomes anæmic through loss of blood, cachexia, or poisoning, there is the same relative diminution of potash as in scurvy, which bears the same relation to the diminution of globular elements. In answer to Dr. Garrod's statement that scorbutic patients are cured by the addition of potash to the food, without the help of fresh vegetables and succulent fruits, M. Villemin asserts that the success attributed to the use of potash, as to other methods of medication, is due to the fact that scurvy takes a natural and spontaneous course towards cure when the patient is placed under favourable conditions, and outside the medium in which the affection prevails. Scorbutic patients treated on the expectant plan recover just as soon as those treated by salts of potash or by succulent fruits. Dr. Garrod's theory does not, in M. Villemin's opinion, explain all the symptoms of scurvy. What is attributed to deficiency of potash is the effect of agglobulism. In other affections hæmorrhages are produced, which cannot be regarded as being due to a diminution of this alkali. M. Villemin holds that scurvy is always epidemic or endemic, and never sporadic. Cases of purpura, hæmophilia, and leucæmia, in which hæmorrhagic effusions constitute a common symptom, are often put down to scurvy. The scorbutic affection is a zymotic and contagious one, the primary focus of which is the septentrional regions of Europe. It follows the same laws as the recognised epidemic diseases; and the above-mentioned favourable influences, to which the majority of observers have attributed the power of creating it, are regarded by M. Villemin as accessory, secondary, and contingent circumstances, which by themselves are incapable of determining scorbutic symptoms. He thinks that he is able to demonstrate that it is impossible to concede to these conditions such an importance, and their only part is to assist and favour the activity of a special morbid agent. These conditions are debilitation of the organism by previous maladies and by defective alimentation, overcrowding, cold, humidity, and, in general, all that is comprised under the denomination of unfavourable hygienic influences. In conclusion, M. Villemin endeavours to show that there is a close pathological analogy between scurvy and typhus fever, and holds that these two ought to stand side by side in the family of miasmatic infecto-contagious diseases.

W. JOHNSON SMITH.

HIRTZ ON ACUTE PHLEGMONOUS PERIOSTITIS, WITH ULCERATIVE ENDOCARDITIS.—M. Hirtz, in the *Progrès Médicale*, p. 413, reports a case occurring in a girl eight years old. Up to five years previously she had never had any ailments, when she was suddenly seized with pain in the left thigh; an abscess formed which was opened and healed in a fortnight. Four days previously to her entry into the hospital the child was suddenly attacked with violent headache. She became delirious the same night, and continued so. At the same time the left thigh began to swell and be painful. On admission, the patient was very restless; she lay on her back with her eyes fixed, and had sudden attacks of terror. The chest-sounds were normal, the heart-beats very rapid. The left thigh was swollen and

painful to the touch. M. de Saint-Germain diagnosed phlegmonous periostitis. He thereupon made a deep incision, from which blood and a little pus escaped. The child sank on the fourth day after admission. The necropsy showed the periosteum thickened and separated for the whole of the lower third of the femur. The surface of the bone was rough, covered with osseous stalactites, and a thin layer of pus. A section displayed islets of osteomyelitis. The meninges of the brain were congested. In the left lung, at its base, was a small infarctus. The right side of the heart was sound. Just below the aortic valves were three small ash-grey ulcerations, surrounded by red zone.

W. C. GRIGG, M.D.

SURGERY.

ASHHURST ON LAPAROTOMY, OR ABDOMINAL SECTION, AS A REMEDY FOR INTUSSUSCEPTION.—Dr. John Ashhurst, junior, surgeon to the Episcopal Hospital, New York, has published an article on this subject in the *American Journal of Medical Sciences*, July, 1874. In the author's work on the *Principles and Practice of Surgery* (published in 1871), he expressed an unfavourable opinion of the operation of abdominal section in cases of intussusception or invagination of the bowels, though he regarded it as a perfectly legitimate procedure in cases of acute intestinal obstruction from other causes. The recent publication of Mr. Jonathan Hutchinson's successful operation for intussusception in a child two years old, has induced him to reconsider the whole subject and to look more carefully into its literature; and the result of this further research and reflection is that Dr. Ashhurst no longer considers the operation as 'never justifiable,' although he still holds to the opinion that it can only be properly resorted to in very exceptional cases.

In order that there may be no confusion in the terms used to describe differing operations upon the abdominal cavity, Dr. Ashhurst, following other recent authors, advises that the words gastrotomy and enterotomy should be held to mean only opening the stomach and small intestines respectively. Laparotomy (from *λαπάρα*, the soft part of the body below the ribs, and *τέμνω*, I cut) is used to signify an exploratory opening of the abdomen, which may or may not involve an incision into the bowel; when the latter occurs, laparo-enterotomy would be the correct designation of the operation. The author then goes into the history of the operation, which it is commonly said was first suggested by Praxagoras of Cos (one of the Asclepiadæ, who flourished about three and a half centuries B.C.); and this is probably true, but there is no evidence that the Greek surgeon ever performed laparotomy. The next reference to it appears to date no further back than the seventeenth century, when Paul Barbette, a surgeon of Amsterdam, after describing the symptoms and pointing out the hopeless nature of intussusception, asks 'Whether it would not be better, having made a dissection of the muscles and peritoneum, to take the intestine with the fingers and draw it out, than abandon the patient to certain death?' Dr. Ashhurst gives, more or less at length, the details of thirteen cases of invaginated bowel for which laparotomy, or laparo-enterotomy, was performed, commencing with the case of the Baroness L., related

by Bonetus, and ending with the case described by Mr. Hutchinson.

The deaths in these thirteen cases were eight. The number of cases he has collected the author thinks the largest ever published, and, though too small to be of much value for statistical purposes, sufficient to enable him to draw conclusions of some value as to what cases may hereafter be submitted to this mode of treatment with a reasonable hope of benefiting the patient.

In the first place the author says, no encouragement is afforded to repeat the operation in very young infants. The only cases in which it has been resorted to during the first year of life have all terminated fatally (three in number, the operators being Gerson, Spencer Wells, and Weinlechner). He then quotes from Pilz's 162 cases of intussusception, all occurring in childhood (to be found in Schmidt's *Fahrbücher*, vol. cxlvi. s. 178), to show that no fewer than ninety-one were infants under a year old, so that a large proportion of the cases must be at once put aside as unfitted for operative treatment. The fatality at this age is very great when no operation is performed, as proved by Leichtenstern's statistics, which show that the mortality is no less than eighty-six per cent.; but, as even at this early age a certain number do recover without operation, and all have died who had been operated on, the author is of opinion that surgical interference is not admissible. Dr. Ashhurst goes on to point out that in acute cases, those namely, in which in addition to symptoms of obstruction there are evidences of strangulation, such as peritonitis and intestinal hæmorrhage, a resort to an operation can be productive of no benefit. These cases are, on the other hand, as justly remarked by Mr. Hutchinson, precisely those in which there is most hope of recovery by sloughing of the invaginated portion. This point is well illustrated by Leichtenstern, who finds that, of 557 cases of which the termination is shown, sloughing occurred in 149, of which eighty-eight ended in recovery and sixty-one (forty-one per cent.) in death; while of 408 in which sloughing did not occur, only sixty-three terminated favourably and 345 (eighty-five per cent.) in death.

There remains, then, says the author, a limited number of cases, in adults or at least not in very young infants, in which the symptoms are those of obstruction merely, without intestinal hæmorrhage or peritonitis, and in which, when other measures fail, the question of operation may properly be considered; and should an operation be undertaken, he is of opinion that *abdominal section* should be chosen rather than either *enterotomy* or *colotomy*, as these could at best give but temporary relief, and have never proved of permanent value in any case of intussusception; whereas laparotomy, as seen by the cases related, has already proved successful in five instances.

To sum up, the following conclusions of Dr. Ashhurst may be thus stated.

1. Past experience gives no encouragement to operative interference in cases of intussusception occurring in infants less than one year old.

2. When the symptoms present, and particularly the existence of intestinal hæmorrhage, render it probable that the closeness of the intussusception will lead to sloughing of the invaginated portion, no operation can be of any service, and there may be a fair hope that the separation of the invaginated mass may lead to spontaneous recovery.

3. There may be, however, exceptional cases, in which, while there is no prospect of recovery through sloughing, bloodless remedies fail to give relief, and the patient is in danger of succumbing through exhaustion and long-continued suffering; under such circumstances, if the age and general condition of the patient do not forbid it, the question of operative interference may properly be considered.

4. When an operation is determined upon, laparotomy should invariably be preferred,

5. In cases of acute intestinal obstruction (from other causes than intussusception), should milder measures fail to give relief in the course of three or at most four days, laparotomy should be unhesitatingly recommended, and may under such circumstances be resorted to with a reasonable hope of success.

[It appears to the reporter that, as long as operations in cases of intestinal obstruction from any cause are postponed until it can be said 'Nothing more can be done,' so long will the fatality attending such operations be enormous. If anything can be done by the surgeon, in these almost hopeless cases, it can only be effected by an early interference, before gangrene and peritonitis have commenced. In most of the cases which have been cited by Dr. Ashhurst and others as weighing against operative interference, the operation was evidently undertaken only as a 'dernier ressort,' and the probability of success was exceedingly small indeed.—*Rep.*]

WM. ALLINGHAM.

DUPLAY ON HYPOSPADIAS.—In the *Journal de Thérapeutique* we find an interesting account of a communication made by Dr. S. Duplay to the sitting of the Société de Chirurgie, on January 28, 'on the treatment of scrotal and perineal hypospadias.' M. Duplay had treated three patients affected with this deformity. Their ages were four, four and a half, and twenty-one. In all, the penis was tightly tied down to the scrotum by a bridle, continuous with the borders of a gutter on the lower aspect of the glans, which is the rudiment of an urethra. The first step in the surgical treatment of the disease is to divide this bridle, and bring the penis up to the belly. The fibrous envelope of the penis is to be freely dissected from the skin of the scrotum, the organ raised and maintained against the abdomen during the whole time of cicatrisation, and for long afterwards. In the case of the young man of twenty-one, two months after the completion of this process sexual intercourse, which was previously impossible, could take place.

A new canal must then be created. This Dr. Duplay only tried on the two older patients; the child of four years having been withdrawn from his treatment. He insists on the necessity of effecting this by gradual processes; and especially on not attempting to unite the new canal to the orifice of the posterior part of the urethra for a considerable time. The meatus, however, may be formed at the same time that the penis is elevated. For this purpose, the borders of the groove are to be pared, and the tissues united over a sound which is left in. Then the new canal is to be formed by dissecting flaps from the under surface of the penis towards the median line, on each side, uniting them in the middle line (of course with their bleeding surface outwards), and then covering them with a flap of skin taken from the neighbouring part of the penis, and raised up sufficiently to glide over the

former. This process did not succeed at once in either patient. In the young man, three operations were needed; in the child, four. In fact, it seems doubtful whether it should be done in childhood, children being apt to tear the wound open. The union of the new canal with the old had only been attempted in the man, and then not with complete success. However, only a slight fistula was left, and when he passed urine without raising the penis, the greater part escaped by the new meatus. Whether the semen also passed by the meatus is not specified.

[The result certainly seems better than any which has as yet been obtained, and may encourage renewed attempts to cure this distressing malformation.—*Rep.*]

ROGER ON ASPIRATION IN THE TREATMENT OF STRANGULATED HERNIA.—In the *Gazette des Hôpitaux*, no. 98, Dr. A. Roger speaks of the practice of pneumatic aspiration in the treatment of strangulated hernia. His opinion is that surgeons have not, as yet, derived all the benefit from this procedure which it is capable of affording, in consequence of their having shrunk from reducing the hernia after having punctured the intestine and evacuated its contents. He proceeds to relate a case in which he was called in to a woman, aged forty-four, who had suffered for three days from strangulation of a femoral hernia. The hernia had been frequently the seat of somewhat similar symptoms, which had disappeared spontaneously. On this occasion, the patient, though she suffered from constipation, vomiting and colicky pains, was free from any more formidable symptoms. Reduction was tried twice ineffectually. The surgeon, not having the apparatus of Dieulafoy at hand, used a common subcutaneous injection syringe (Pravaz), which he plunged (under chloroform) into the tumour at the point where it seemed least resonant. The point of the instrument seemed free in a hollow space. Some clear watery fluid, with a faint odour, escaped. Of this, he withdrew forty charges of the syringe, equal, as he calculated, to thirty-eight grammes, and then succeeded in reducing the hernia. An injection of salt and water was ordered, and produced two motions. The bowels acted spontaneously next day, and the patient recovered without any bad symptoms.

Dr. Roger remarks on the peculiar character of the fluid evacuated in this case, and refers to a case under M. Richet's care in which similar liquid was extracted from a hernial sac. He believes that in his case it really came from the interior of the gut, since one or two bubbles of air were mixed with it. He calls attention also to the convenience of performing this operation with an instrument so common and so simple as Pravaz's syringe.

PROMPT ON SALIVARY FISTULA.—In a recent number of the *Gazette des Hôpitaux* (p. 814) is the account of a patient who was exhibited to the Académie de Médecine after the cure of a salivary fistula. He was a boy aged twelve, who fell in running down a staircase with a chamber-pot in his hand. His cheek was cut, and three fistulous openings formed—one corresponding to the situation of Stenon's duct, which showed no tendency to heal, the two others situated over the gland itself closed spontaneously. An artificial canal was formed through the cheek, by means of a trocar, and kept

dilated with tents and bougies. When this canal had been completely established, the wound was closed by twisted suture. The cure at the time of exhibition (more than three months after the accident) seemed complete. During the presence of the fistula, Dr. Prompt, his medical attendant, made several observations on the boy which led him to the following conclusions.

1. The discharge of parotid saliva depends on the excitation of the sense of taste, and is pretty nearly the same whatever be the form of that excitation, whether the person eats or drinks, or a sapid substance is applied to the tongue.

2. The quantity of the liquid secreted depends chiefly on the time during which the excitation of the sense of taste lasts; thus, if a glass of wine is swallowed at once, only a few drops will be secreted; if it be drunk in small mouthfuls, so as to spend three or four minutes over it, a considerable quantity, as much as two or three grammes, will be obtained.

GUILLAUMET ON RUPTURE OF THE GLUTEAL ARTERY.—A case of rupture of the gluteal artery, leading to what is termed 'a false consecutive aneurism' is related in *Le Progrès Médical*, as having been brought before the Société Anatomique on March 6, by M. Guillaumet. The patient, a criminal, aged twenty-five, was admitted into hospital on February 14, 1874, in a state of extreme general anæmia. He had extensive disease of the heart, and the arteries over the whole body pulsed very violently, but without any tumour or bruit. In the right buttock was a 'hard fluctuating' tumour ('tumeur dure et fluctuante') about two-thirds as large as the head of an adult. It seemed to be beneath the muscles; the skin was smooth, tense, and shining, the veins enlarged but not varicose. There was tenderness to the touch, the whole mass presented pulsation, and a strong souffle was audible over the whole of it. No cause was known for the disease. He had fallen about six feet, and struck his right buttock against a piece of furniture ten months before (April, 1873), but had not experienced any particular inconvenience. He was put into prison a short time afterwards. The tumour had made its appearance a month before (January, 1874), after an unusual exertion. The tumour had been punctured, about a fortnight before his admission into hospital, with a bistoury, causing a small wound, which was still visible. According to the man's account, a clear serous fluid had escaped from this wound. The wound had afterwards bled a good deal, though not to any really alarming extent, and the anæmia dated from that time. After his admission an exploratory puncture was made by M. Th. Anger (under whose care and that of M. Legroux the patient was), and this gave exit to pure blood. Accordingly the disease was diagnosed as aneurism, and it was decided to inject it with perchloride of iron. But secondary hæmorrhage came on from the wound, which it was impossible to repress, and the man died in a few days. *Post mortem* examination showed extensive disease of the heart, and a good deal of atheroma of the large arteries. On dissecting the buttock, the muscles were found infiltrated with blood, and below them was an enormous cavity filled with clot partly laminated, or 'active,' as the author calls it, on detaching which the ilium was found exposed and eroded. The gluteal artery was open, as if cut with a knife, just at the level of the posterior lip of the sciatic notch, the edges of the ruptured part being rounded

off, something like those of a glass tube which has been melted in a lamp flame. Traces of atheroma were seen on the edges of the ruptured part. The lower end of the ruptured artery could not be found.

M. Legroux observed on the difficulties of the diagnosis, which could only be cleared up by exploratory puncture, and then discussed the question of treatment. Compression, he says, was impracticable; the application of ice could not produce any particular result; the opening of the sac and direct ligature of the artery, as practised by J. Bell Carmichael and Warren Stone, was too dangerous. There remained the injection of perchloride of iron, which was decided on under the authority of Nélaton's case, but the examination of the tumour shows that this would have failed, and the only effective measure would have been the ligature of the internal iliac, an operation, however, which could hardly be thought of in the man's condition. [In fact, it seems clear enough that the disease was absolutely incurable. Ligature above the rupture would in all probability have failed to check the hæmorrhage,* and the direct ligature of both ends of the vessel was apparently impracticable. It is, however, the only trustworthy measure in these cases of ruptured artery, which are very different in practice from aneurisms, though unfortunately they have received that name.—*Rep.*]

Finally, M. Legroux speculates on the cause of the disease, believing that the artery, originally diseased, was injured by the fall, or possibly was ruptured at the time, and a small aneurism formed, which passed unperceived until either it or the contused artery gave way, at the time of the extra exertion, and the blood was poured out into the tissues of the buttock.

[It is worth the while of any one interested in this subject to peruse along with this case, Mr. Morratt Baker's above referred to, and Servier's, in the *Gazette Hebdomadaire* for 1868. The latter especially bears a great resemblance to the present case, and it is rather singular that it is not mentioned.—*Rep.*]

T. HOLMES.

SYPHILOGRAPHY.

JACKSON ON SYPHILITIC DISEASE WITHIN THE CRANIUM.—Dr. J. Hughlings Jackson has reprinted, from the July number of the *Journal of Mental Science*, 'Two Cases of Intercranial Syphilis.' [Lewes: G. P. Bacon, p. 12.] Much attention has lately been given to the rôle of syphilis in the production of grave lesions of the nervous system. Drs. Bristowe, Broadbent, Buzzard, Moxon, and Wilks, have all recorded cases, though, if we mistake not, Drs. Merryon and Ogle were among the first to specially direct English attention to this subject. On the continent, Gros and Lancereaux, Virchow and Wagner, with others too numerous to mention, have for some years past specially studied this question. So important indeed is it now considered, that Bäumlér tells us that it is to form a special division of Von Ziemssen's *Handbuch des Speciellen Pathologie und Therapie*. Numerous papers by Dr. Jackson in the *Medical Times and Gazette* ever since 1861, his 'Study of Convulsions' in the *Transactions of the St. Andrew's Medical*

Graduates' Association, vol. iii. p. 162, and the articles by him in the *London Hospital Reports* on diseases of the nervous system, show that he has made this subject one of special study. The conclusions drawn after so many years of observation deserve at least the most careful consideration, and a wider publicity than they are likely to gain in a pamphlet form. Dr. Jackson lays down two or three general principles, or canons of criticism, in such cases, which at first sight seem somewhat contradictory. The first is (p. 1 of the pamphlet), that 'a random association, or a random succession, of nervous symptoms is very strong warrant for the diagnosis of syphilitic disease of the nervous system.' Of course this syphilis may be inherited, or if acquired, may have been so quite irrespective of the patient's knowledge that he has so acquired it. The second canon is, that 'double optic neuritis with one-sided convulsions, do point, in most cases, to syphilitic disease of the cerebral convolutions, to coarse gummatous deposits; the neuritis alone, or the convulsions alone, not having the same value.' At first sight these propositions seem in slight contradiction, the lesions of the latter being seemingly quite definite. But reflection shows us that the association is random, and thus the first canon is unimpeached. The first case narrated was a soldier, aged thirty, who had had complete paralysis of both third nerves for five months. The patient denied having syphilis, but the testes were never examined, which Dr. Jackson thinks should always be done in doubtful cases. Convulsions followed, which were not seen by any medical observer; next (nine months after first attack), hemiplegia of the whole right side—face, arm, leg. His intellect became somewhat deranged; and three months after, he was attacked with hemiplegia of the left side, and died four days after, in a state of coma. Both pupils became small and equal before he died. There were two suspicious (yellow-white, wash-leather like) nodules in one testis, and several puckered cicatrices in the liver. Examination of the brain and its arteries showed gummatous deposits, involving the last quarter inch of the right vertebral artery, the basilar, for about one-fifth of an inch, the left vertebral artery and the rootlets of the ninth nerve (just a little before death he seemed unable to move his tongue); the left anterior cerebellar artery ran back parallel to the left vertebral, and was glued to it, as also to the sixth nerve. The anterior fifth of the basilar was here and there affected, whilst both posterior cerebral, and both superior cerebellar arteries and the two third nerves were all fixed to one another by material similar to that thickening the arteries. All the arteries at the base seem to have been more or less affected, whilst through the arachnoid, over the inner end of the right fissure of Sylvius, was seen a yellowish mass, the size of a horse-bean. The right middle cerebral artery was enlarged and nodose, and it and all its branches were welded together. The left middle cerebral was also thickened, and its principal branches a little nodose. Both these vessels, however, were pervious. Both anterior cerebral arteries were blocked. The floor of the fissure of Sylvius was imperfectly softened for about an inch from its commencement (right side?). On the inner and anterior part of the right corpus striatum there was depression, and below this, softening of the size of a hazel-nut. The left corpus striatum was softened in the lower and external

* See Mr. Morratt Baker's case in *St. Bartholomew's Hospital Reports*, vol. viii.

part, and the lower part of the thalamus was slightly softened.

The second case was that of a man aged forty-five, suffering from intense pain in the head, who had double optic neuritis and convulsions. He denied syphilis, but his only living child, a girl of twelve, who also had convulsions, had nebulous corneæ (? post-interstitial keratitis), and notched central upper incisors; her nose was also sunken. She died of typhoid fever, but no visceral lesions of syphilis were discoverable. The father recovered from one or two attacks of cranial pain, followed by more or less stupor, and convulsions under large doses of iodide of potassium. A year after his first attack he had palsy of the right face, and the left arm and leg were weak. The facial paralysis was unlike Bell's, more like hemiplegic. Six weeks after, the left third nerve was paralysed; he recovered to a great extent with fifteen-grain doses of iodide of potassium three times a day, after about two months, but on going out was soon attacked with right hemiplegia, with deviation of the head and eyes to the left. He got more and more comatose, a bed-sore formed, and the sphincters were affected. Death followed in about six weeks. Here also gummata and softening were found both in the brain and in its arteries. For the details reference must be made to the pamphlet. As regards treatment, Dr. Jackson admits that the effects of antisyphilitic remedies, such as iodide of potassium, which should be given in large doses, is often striking, but he is not very sanguine as to their having much share in the recovery from the nervous symptoms. Still, he thinks it right to treat syphilis whenever we find, or reasonably suspect it, but he says: 'If we keep an eye on our patients, we find them suffering again; we often "cure" them many times,' (*Med. Times and Gazette*, March 29, 1873).

His third canon is: 'A patient who has recovered from a syphilitic affection of the nervous system is very likely to suffer again—not necessarily from the same kind of symptoms, but more likely from a new style of symptoms.' Of this numerous cases reported by Dr. Jackson and others in the different journals, especially the *Lancet*, *Medical Times and Gazette*, and *British Medical Journal*, afford such numerous proofs that it seems sufficient to quote without comment. W. BATHURST WOODMAN, M.D.

DERMATOLOGY.

MALASSEZ ON THE FUNGUS OF ALOPECIA.—M. Malassez (*Revue des Sciences Médicales*, July 15, 1874) says that since 1843, when M. Gruby announced to the Academy of Sciences that he had discovered a parasitic fungus in the form of Tinea, called Porrigo decalvans, and that he considered this parasite (*Microsporion Audouini*) as the cause of the disease, micrographers and dermatologists have sought in vain for Gruby's fungus. Indeed the parasitic character of alopecia has always been a matter of doubt; some have denied the presence of the parasite in this disease; others, with a view to demonstrate its existence, have relied on the clinical development of the disease rather than on the verification of the actual presence of the parasite.

This parasite exists however, undoubtedly. M. Malassez has found it on the scale of epidermis obtained by scraping the patches of alopecia on the

skull. These scales, freed from grease, then washed in very pure absolute alcohol, and mounted in carbolic acid (1 in 100) showed unmistakable parasites made up of small spherical spores only. Three distinct types of these parasites can be made out. Those of the first type measure from 4 to 5 millimètres, have a double contour, and sometimes show buds with a simple contour; these are the large spores. Those of the second part measure from 2 to 2.5 millimètres, have not a double contour, but may have buds; these are the small spores. Those of the third kind are less than 2 millimètres in diameter, have a single outline, and no buds; these are the sporules.

There are not any tubes, only little chains of, at the utmost, five or six spores. The spores of the first two varieties (both large and small) sometimes take the form of a more or less open C; these are the dead, empty spores—skeletons of spores. The sporules never present this appearance. The large spores and the sporules are grouped irregularly on the patches of epidermis. The small spores most frequently take the form of small chains. Finally, agglomerations or patches of these spores are observed, especially round the hair-follicles, which they surround like a border. The isolated spores are young colonies; seed sown here and there for future development. The patches are probably old centres of propagation. The spores are very seldom seen on the hair. When they are found there it is always on the surface of the shaft; they do not ever directly adhere to the hair, but to the neighbouring epithelial cells. They thus form a more or less complete chain or ring round the hair, and undoubtedly take their rise from the cutaneous epidermis.

The hairs are sometimes discoloured, atrophied, and brittle; but their structure is not sensibly modified, neither is the epithelium destroyed. Microscopic preparations of the skin clearly show that this parasite only locates itself in the most superficial parts of the horny layer; it frequently insinuates itself between the layers of epidermic cells which they detach mechanically in the form of scurf.

At the level of the patches of porrigo, near the orifices of the hair-follicles, the favourite habitat of the parasitic ring, the epidermis becomes considerably thickened, sometimes attaining fifteen times its normal thickness; in fact, a true *pityriasis pilaris* is developed, which interferes mechanically with the nutrition of the hair, strangles its growth, and destroys it by enlarging the follicle and producing desquamation, whence arises porrigo decalvans.

E. LAWSON.

PSYCHOLOGY.

NEWINGTON ON HEMIPLEGIA IN RELATION TO INSANITY.—In the *Edinburgh Medical Journal*, of August, 1874, Dr. Hayes Newington considers the subject of 'Hemiplegia in relation to Insanity.' Hemiplegia, as it is met with in asylums, may be divided into two classes; the first containing those where the seizure may be regarded as accidental, the other embracing those where the attack is the cause, result, or complication of the psychical disorder.

1. Where each individual patient labours under some form or other of brain-disorder, hemiplegia may be expected to occur frequently. The com-

monest naked-eye pathological change in a lunatic's brain is atheroma of the vessels; and in the aorta, or on the semilunar valves, patches of deposit are found in the majority of cases. And yet rupture of vessels is not much more common in asylums than out of them, owing, probably, to the regular and restricted diet, sedentary habits, and a blunting of all the emotions which ordinarily disturb the vascular supply.

2. In the second class of cases there is an obvious relation between the psychical and the physical disease. Hemiplegia has given a name to a variety of mental disease. This has been called 'paralytic insanity,' and always assumes the type of dementia. It is not to be confounded with general paralysis of the insane. Of this insanity hemiplegia will not, usually, be the only cause. Predisposition, hereditary or acquired, is necessary, and alcohol is a very likely form of the latter.

Hemiplegia is more frequently found as a result of insanity. It is common to see a patient down on one side, limping along, with obliquity of the tongue and inequality of pupils. In the course of a few days we find him as free from motor troubles as any of his neighbours, and hear that he has had an epileptic or epileptiform seizure prior to the symptoms, or has been excited or noisy at night. The cases of this evanescent hemiplegia may be divided into two classes:

a. Cases where the paralysis is independent of a convulsion of any kind, but supervenes on an attack of excitement. Here, probably, the hemiplegia is due to minute extravasation of blood into the optic thalamus and corpus striatum. Symptoms so caused may rapidly pass away. An extravasation need not necessarily disintegrate brain-structure irremediably. If of small size, it may split up and separate without destroying the nerve-fibres, leaving a chance of their resuming their duties.

b. Cases where a convulsion precedes the paralysis. This class is composed of epileptics, general paralytics, and patients suffering from adventitious products in the brain.

As to these cases, Dr. Newington quotes Niemeyer's opinion, that by far the greater portion of injury done to the motor system is due to extravasation not of blood, but of serum; and nothing seems more probable than that such should be the fact, when, as in epilepsy, there is great and continued pressure exerted on diseased vessels, and when also no evidence of hæmorrhage or obstruction is found; while, on the other hand, dilatation of vessels and waterlogging of the brain-substance is a very common discovery. It is to this effusion, occurring partially, that he would attribute the evanescent hemiplegia in this class of cases.

G. FIELDING BLANDFORD, M.D.

EPIDEMIOLOGY.

VARIOLA PROPAGATED BY VACCINATION.—In the *Gazette Médicale de Strasbourg* of July last, there is an account of an epidemic which was propagated by vaccination. 'On May 3, 1872,' (says the article from which we quote), 'twenty-four infants at the breast were vaccinated from a child three months old. All became sick, more or less, towards the end of the first eight days, and some were unable to present themselves for examination on May 10. On

this day twenty-three other children were vaccinated from one of the first batch, in whom the vaccinia was normal (ayant une vaccine normale et exempte d'éruption quelconque). These last experienced the same febrile symptoms, and all the children, without exception, the two vaccinifers included, were seized from the eighth to the eleventh day of the vaccination with an eruption presenting the following characters.

'Reddish pale papules of the size of a pin's head were spread over the whole of the body, accompanied by fever; two days afterwards vesicles were formed filled with a whitish liquid, and their extension upon the mucous membrane of the nose and mouth rendered the voice indistinct (voilée) and deglutition difficult.

'Let us note, too, that everywhere the vaccinia had followed apparently its normal course, and that the pustules, without being very good, had their characteristic aspect. Twenty-six infants, more advanced in years, were re-vaccinated of these two vaccinifers, and many among them were seized some days afterwards by a fleeting rash of short duration, resembling urticaria.

'The exanthem of the infants was characterised by its results. It became the point of departure of a small-pox epidemic, which commenced among the mothers and the members of the families of the said children, and which was propagated with such rapidity, that from May 15 to June 19 there were seventy-five cases, not including the vaccinated children. On July 30 the epidemic was considered to have terminated, after having attacked 141 persons, which, with the forty-seven vaccinated, forms a total of 188 persons in a population of 3,000.

'The disease was severe; three of the cases being hæmorrhagic, of which two died; of the whole number, nine died, eight adults and an unvaccinated child.

'It is clear,' said one medical man, 'that these vaccinated children were under the simultaneous influence of the poisons of vaccinia and variola. This is a well known fact; but how is the explosion of the variola to be explained in these forty-eight children. One cannot admit that they were incubating variola at the time of their vaccination; that might happen in isolated cases, but not in two large groups. Moreover, the simultaneousness of the appearance of the exanthem, each time from the ninth to the eleventh day of the vaccination absolutely negatives this supposition and connects the variola with the vaccination.

'Direct official information and special inquiries showed that the child that served to vaccinate the first vaccinifer was free of all small-pox eruption; but at this period there was small-pox at Oedt, and a relative of the first vaccinifer was sick of it. On the eighth day of its vaccination, when it had served the first group of May 3, this infant had small-pox, but still in the incubation period; its blood was contaminated, and the variolous virus, it was urged, might have been produced in the vaccine pustule, as in syphilitic vaccination.'

The writer of this article rejects the notion that the variola might have owed its existence to contagion, inasmuch as if that notion were true the mothers as well as the children would have suffered; as also the notion that the variolous virus was inoculated along with vaccine virus. He maintains that the facts are most simply explained by admitting

that the first vaccinifer had undergone variolous inoculation. Quoting from an old treatise on the history and practice of inoculation (Dézoteux et Valentin; Paris, an. viii), he thus describes that process: 'First period: Eruption local. In the five or six first days which follow the insertion, the variolous virus exercises only a local action, and determines an eruption of pustules in the inoculated places, named local or primitive eruption. This local and primary eruption is a true small-pox, special to the inoculated part.'

'The second period, fever of invasion, commences ordinarily at the end of the seventh day, or in the eighth, dating from the moment of insertion. At the end of the third, or at the commencement of the fourth of this fever, that is to say the tenth or the eleventh of the inoculation, commences the third period, or that of the general eruption, more or less intense, often reduced to some pustules and of failing altogether.

'Let one compare this description with the vaccinations at Oedt, and one will see a complete identity; towards the eighth day all the vaccinated infants were sick more or less, and from the eighth to the eleventh day they had variolous eruption. It was then variola which was inoculated, but was vaccinia at the same time. There is no evidence for or against, for no one to-day can demonstrate directly the nature of the pustules of insertion of the first vaccinifer; one can only do so by a rigorous analysis of the consequences of their propagation, and that indicates nothing but small-pox.'

ALEX. COLLIE, M.D.

MISCELLANY.

CREMATION.—At Breslau, on September 22, a large number of members of the Association of German Naturalists and Physicians assembled to witness the burning of a human body. The body was that of an old woman who had died in the hospital. In half an hour after the body had been placed in the gas oven, the soft parts had almost entirely disappeared; and at the end of an hour, besides the heated bones, there was nothing left but the remains of the liver, which required another hour and ten minutes for complete combustion. The time of burning was prolonged, as the opening in the door for the purpose of observation allowed the entrance of air and consequent cooling of the chamber. The weight of the body was seventy and a quarter (German) pounds; the ashes of the bones weighed three pounds.

MEDICINE IN RUSSIA.—The *Golos* of St. Petersburg states that in Russia there is but one physician to every 17,800 souls. There are governments such as that of Perm, circles like that of Sherdink, where the proportion is still smaller, and there is scarcely one physician to 60,000 souls. There is, moreover, one hospital to every 175,000 inhabitants; one for women in labour to every 6,000,000, one for foundlings to every 1,350,000; one lunatic asylum to every 390,000, one deaf and dumb institution to every 11,000,000. The Russian journal says that the army is better provided for, there being one hospital to every 5,000 men. In Prussia the proportion is one to 1,250. In Italy there is one physician to every 2,280 inhabitants; in England there is one medical man (surgeons included) to every 3,180.

LEAD IN SODA-WATER.—The following is a further contribution to the literature of this rather interesting domestic subject by Mr. William Taylor of Edinburgh. In 1867 there was a patient admitted to ward 3, Royal Infirmary (medical), suffering from lead-poisoning. He

was employed in an aerated-water manufactory. Aerated water was the vehicle through which the lead had reached his system, and daily potations, *ad libitum*, the means which secured the necessary quantity. His favourite beverage, was, I think, lemonade, and several bottles of it were brought to the hospital for analysis. The presence of lead was detected in it. The patient knew that lead in any form was not introduced by his master as an ingredient in the lemonade. It must therefore have found its way thither as an adulterant amongst the chemicals used in the process of manufacture, or as the result of their action upon the lead pipes through which the manufactured article was conveyed. The patient was under the care of Dr. Warburton Begbie, who was then acting for Professor Laycock. The testing was carefully conducted by Dr. Crum Brown.

AN EGYPTIAN MEDICAL TREATISE.—Among the printed works submitted to the Oriental Congress was a remarkable *fac simile* exhibited before the Hamitic Section by the discoverer, Professor Ebers, of Leipzig. This is a complete book from beginning to end, and in respect to size is only surpassed by the great Harris Papyrus in the British Museum. The manuscript in question is a perfect handbook of Egyptian medical science; and, without pretending that the physicians of our time have much to learn from their embalmed predecessors of the Nile, this papyrus may yet afford them a rich source whence may be drawn the history of their science from its earliest dawn. A calendar on the back of the MS. informs us that it was written in the sixteenth century B.C. We know already that at this remote period Egypt stood in political and commercial relation with the neighbouring States of Western Asia; but the Ebers Papyrus teaches us further that there already existed an interchange of thought and knowledge. Not only a vast number of medicaments procured from Asia are alluded to, but we find also *recipes* borrowed from a celebrated physician of the town of Byblos, in Phœnicia. Other *recipes* are derived from older writings, as, for instance, *The Book of the Wisdom of Men*. The typographical reproduction is the work of the printers, Giesecke and Devrient. By a new process, the 110 pages of which the MS. consists are imitated with surprising fidelity. In about two months the whole work will appear, accompanied by a translation from the hand of the editor, Professor Ebers.

THE ASSOCIATION OF GERMAN NATURALISTS AND PHYSICIANS held its forty-seventh annual meeting in Breslau on the 18th of last month and following days. The proceedings were opened with an address by Dr. Löwig, Professor of Chemistry in the University, the greater part of which was occupied with a notice of the life and labours of the chemist Richter, a native of Silesia, whom Dr. Löwig described as the discoverer of chemical proportions and the founder of the higher scientific chemistry. Addresses of welcome were then delivered by Baron von Nordenflicht, President of the Province of Silesia; Herr von Forckenbeck, chief magistrate of Breslau, and Professor Heidenhain. Professor Virchow delivered a characteristic address on Miracles, with special reference to the case of Louise Lateau. For the transaction of the scientific business of the association no fewer than twenty-three sections were formed, viz: 1. Physics; 2 and 3. Mathematics, Astronomy, and Meteorology; 4. Chemistry and Pharmacy; 5. Agricultural Chemistry; 6. Geology; 7. Zoology and Comparative Anatomy; 8. Botany; 9. Anatomy and Physiology; 10. Medicine; 11. Surgery; 12. Military Hygiene; 13. Ophthalmology; 14. Otology; 15. Diseases of Children; 16. Gynaecology; 17. Psychological Medicine; 18. Public Health; 19. Balneology and Physical Therapeutics; 20. Anthropology and Pre-historic Archaeology; 21. Geography; 22. Agriculture; 23. Pathological Anatomy. Gratz, the capital of Bohemia, was chosen as the place of meeting in 1875. Invitations were also received from Homburg and Kissingen. The proceedings were enlivened

through the hospitable attention of the inhabitants of Breslau, with public dinners, a ball, and excursions to various places of interest.

AN EXCELLENT IDEA.—The *Gazette Hebdomadaire*, in the number published on the 25th ult., urges the necessity for establishing a system of medical stations for night service in Paris. Our contemporary enlarges upon the bad consequences which often arise from the difficulty of obtaining medical assistance in the night, and cites the case of a lady who died after a few hours' illness from a sudden attack attended by some symptoms of poisoning. Her husband, it appears, sought the services of four medical men who lived in his neighbourhood, but in vain; not one of them was at home. When a fifth was at last obtained, it was too late, and the patient died, when she might have been saved by prompt aid. The plan proposed by the *Gazette Hebdomadaire* is, that a night medical station should be established in every municipal district, and should be officered by medical men willing to undertake the duty, one or two of whom should be at the post every night. Every person who came to seek medical assistance should deposit ten francs with an official deputed to receive the same, or be required to make a declaration that he was unable to make such payment. The medical man on duty should then receive proper notice, go to the address given, and on his return would receive a cheque payable at the parochial treasury, so that there would be no question of fees between him and the invalid. In cases of poverty, when the case had been duly verified, the poor-law authorities would defray the medical fees, which in this instance would be reduced by one-half. It appears that these night stations for medical aid are established and in operation in the principal cities of Germany and in Russia. Their utility is both manifest and incontestable.

AN INVOLUNTARY TESTIMONY.—The *French Journal Officiel*, in giving an account of the French explorations in Burmah, goes into the following details respecting the fever peculiar to the woods in that country, which seems to have a strong resemblance to the European typhus fever. 'On July 7, Father Lecomte, French apostolic missionary and curé of Mandelej, received news from Captain Moreau that several members of the escort had been attacked by paludal fever, of which some had recovered. Just, however, as they were setting off again, a youth of eighteen had a worse attack, and died very quickly; his death was followed by that of the cook of the expedition, who was ill for six days, and by that of another youth, whose death was lingering. At the end of the month, nearly the whole of the members of the expedition, with the exception of Captain Moreau and a few others, were attacked. Captain Fau took to his bed for five or six days, with symptoms characteristic of the terrible disease called "fever of the woods" by the natives. Unfortunately Captain Moreau hesitated to give him large and daily doses of quinine, dreading to increase the gastric irritation and comatose condition from which the sick man was already suffering, and which resulted in his death. It would appear that this "fever of the woods" is nothing else but typhus, and is the same disease which killed the famous traveller Henri Mouhot, who explored Cambodia with signal success. Dr. Thorel, who was attached in a medical capacity to the French expedition to Mekong, describes this malady in the medical notes made by him at the time. He had an opportunity of studying it in two cases, one of which recovered well in a moderately short time by the daily administration of a large dose (eighty centigrammes—twelve grains) of sulphate of quinine; the other, whose dose was reduced to sixty centigrammes (nine grains), after the first two days, fell into a desperate state after the fourteenth day. He was perfectly deaf and comatose, and it was necessary to shake him to make him open his eyes. He was believed to be on the point of death towards the end of the fifteenth day, when, eluding the vigilance of his attendant, he threw himself into the river.

He was taken out in time to save him, but not before he had had a cold bath, which cured him with astonishing rapidity; thus affording an unwitting testimony to the efficacy of the disputed treatment of fever by cold affusions.'

AN INGENIOUS CONTRIVANCE.—At the meeting of the French Academy of Medicine on the 22nd ult., M. Delalain showed a patient wearing a prothetic apparatus invented by him, which he calls a facial obturator, intended to conceal an enormous destruction of the substance of the face. The patient was an artilleryman twenty-four years old, who had been wounded in 1870 by a shell which carried away his nose and both his eyes, made a comminuted fracture of the two upper maxillary bones, and lacerated the lower jaw. After having remained more than a year in the hospitals of Arras and Val-de-Grace, cicatrization had made but little progress in consequence of the persistence of suppuration, which the surgeon in charge of the case considered as a formal indication against all attempts at prothesis. However, in consequence of a decision of the Army Medical Council, M. Delalain's prothetic apparatus was applied, and the patient was sent back to his home. Suppuration soon ceased, and the wound soon began to cicatrize thoroughly. The apparatus to which the wounded man owes his cure is principally composed of a mask, the outside of which represents the central portion of the face (eyes, nose, and mouth) which was carried away by the projectile, and is applied exactly over the adjacent portions of the wound. Inside, the mask contains two ventilators, intended to give greater keenness to the smell, a sponge to absorb the excess of humidity in the air in foggy weather, a respirator intended to stop the dust drawn in by inspiration with the exterior air, and a channel terminating at the lobule of the false nose, perforated at the end with several small holes allowing the water from the vapour of expiration to flow out without touching the sound portions of skin on which the lateral edges of the artificial countenance rest. By the aid of this apparatus all the principal functions are entirely re-established, with the exception of sight, which is totally lost. Respiration is again normal and regular; the sense of smell is as keen as ever; the upper jaw, consolidated by a plate which doubles the palatal vault, affords sufficient resistance to allow the mastication of the most solid food; and even the voice, which had become nasal, has regained its natural tone.

MEDICINE IN SWEDEN.—An interesting article on the recent Archæological Congress at Stockholm, by M. Albert Kobin, published in the *Journal de Thérapeutique* for September 25, gives some details respecting the hospitals and medical schools of Sweden. It appears that in that country there are seventy-nine hospitals, containing 4,687 beds; receiving an average of from 30,000 to 32,000 patients, with an annual death-rate of about 2,000. The expenses of these hospitals amount to about 40,000*l.* per annum. There are nine lunatic asylums, containing 1,210 beds. In 1870, statistical returns showed 9,109 lunatics, of which 4,666 were men, and 4,443 women. There were also 3,280 blind persons, 1,504 men, and 1,776 women; 4,254 deaf and dumb, comprising 2,370 men, and 1,884 women. Stockholm contains seven hospitals, of which the most important is the Clinical Hospital, containing 300 beds. The wards of this institution are small, low, badly lighted, and in a very indifferent order. It is very difficult to ventilate them; they are therefore about to be replaced by a construction on the pavilion plan. At the head of each bed is a small black tablet, on which the clinical clerk writes his chief's remarks every day. The surgeons have begun to use the wadded splints, but find it difficult to give up the use of Lister's bandages, which they have unanimously adopted. In Norway they employ a method of dressing wounds which was used by the Americans in the war of secession. Lint and wadding are replaced by fine tarred oakum, the bandages and other portions of the dressing being impregnated with acetate of alumina. This method of treatment yields excellent results, and Dr.

Thaulow of Christiania employs it in his wards to the exclusion of any other. The only specialty to be seen in the medical wards is the plan used for the cure of acute affections of the chest, such as pneumonia and acute bronchitis. It consists in making the patient constantly respire air, holding in suspension a large quantity of aqueous vapour; the bed being entirely covered with a moderately thick cloth, in which two apertures are made for the renewal of the air. A water vapouring apparatus is placed at the foot of the bed, to the level of which the vapour is conducted by a tube. This method of medication, which, however, is not new, is tolerably successful, especially in children's cases.

THE SCHOOL OF MEDICINE FOR WOMEN.—For some time past a movement has been in action to establish a school of medicine for women, the early promoters being the late Dr. Anstie, Dr. T. K. Chambers, Mr. A. T. Norton, and Mr. Ernest Hart. The plans for the school are now so far matured that it will be opened for the winter term on October 12, in commodious premises at 30 Henrietta Street, Brunswick Square, where it is intended to build a detached dissecting room in the garden attached to the house. The full staff of lecturers has not yet been appointed; but among those who have already consented to take part in the instruction are Dr. King Chambers in the practice of Medicine, Mr. Berkeley Hill in Surgery, Mr. A. T. Norton in Anatomy, Dr. Sturges in Materia Medica, Mrs. Garrett Anderson in Midwifery, Mr. Crichton in Ophthalmic Surgery, Dr. Cheadle in Pathology, Mr. Heaton in Chemistry, and Mr. A. W. Bennett in Botany. The following gentlemen have, in addition, consented to serve on the council: Dr. Billing, Dr. Buchanan, Mr. Ernest Hart, Professor Huxley, Dr. Hughlings Jackson, Dr. Murie, Dr. F. Payne, Dr. W. S. Playfair, and Dr. Burdon-Sanderson, as well as Dr. Elizabeth Blackwell. By the establishment of this school for the separate education of women wishing to enter the medical profession, one of the objections most strongly urged against their prosecution of the necessary studies, viz., their being obliged to obtain their education in mixed classes, will be obviated, and the question as to the fitness of women for the practice of medicine and surgery will be nearer to a practical solution. A fair number of students have already entered their names.

The lectures will be delivered in the house, No. 30 Henrietta Street, Brunswick Square; but the practical anatomical course will not be delivered there. The courses which will be immediately commenced there are those of Chemistry, Anatomy, and Physiology. This step has been taken as a means of overcoming the objections which have been urged to the admission of women to medical education on the score of alleged difficulty in establishing separate classes. It is, however, by no means certain that the present effort will end the difficulties of the women who desire to obtain the right to practise medicine in England. The last public act of the late Dr. Anstie was to apply, in his capacity of Dean of this school, to the Medical Examining bodies of London for recognition of this school as a duly constituted teaching body. Without recognition, the lectures of the school, although all delivered by gentlemen who are 'recognised' elsewhere, will not count for degrees, and the students will not be admitted to examination. It would be a singular anomaly if it should be decided that a body of gentlemen whose lectures are all 'recognised' when they are lecturing to men should be refused 'recognition' when they are lecturing to women. But it is by no means impossible that this will be seen.

THE CRY OF THE CHILDREN.—Public attention in France has been much directed of late to the great decrease in the population during the last eight years. The census of 1872 shows a diminution of 370,000 since the census in 1866. Among the causes assigned for this remarkable decrease are, the enforced celibacy of the large standing army of France, the diminution of births in the marriage state, and lastly, the excessive mortality

among infants. One of the first medical men who called attention to this neglect, M. Brochard, affirmed in 1866 that reckoning pauper children, 100,000 nurse children died annually in France of hunger, privation, want of proper care, and want of superintendence. The Academy of Science endorsed this statement by crowning the work in which it was embodied. Soon after, M. Felix Boudet renewed this sad accusation, by declaring before the Academy of Medicine that France loses every year by its own fault 120,000 young infants under one year old. This first stage of life gives a considerable proportion of death-rate everywhere, and an eminent statistician has given striking expression to this fact in the observation 'that a new-born infant has less chance of living for a week than a man of ninety, and less chance of living a year than a man of eighty.' In France, however, in ordinarily favourable vital conditions, M. Bertillon calculates that, up to one year of age, the death-rate averages 21·7 per 100; that is to say, more than a fifth of the children born die at the end of the first year. In Paris, out of 54,000 children who are born every year, nearly half die before their fourth year; and if the children sent out to nurse be reckoned separately, it will be found that at least one-half (51·6 per 100) have perished in the first year of their life. Finally, if the children be classed according to their position in life, and the kind of nurse with whom they have been placed, the almost fabulous death-rate of from 75 to 80 per cent. is attained, which seems incredible even when we find it stated in official records. The Academy of Medicine has taken up this terrible blot on the civilisation of France, and has issued a code of laws for the protection of infant life. Amongst the causes mentioned in this programme as productive of the general mortality, and which may be reached by legal enactments, are the following:—The want of a system for the verification of the deaths of new-born children and nurse-children; the premature taking-out of infants for the purpose of obtaining the certificates of birth and baptism; the putting them out to nurse; the default of measures, making vaccination obligatory; the absence of any law to regulate taking children in to nurse, and especially for any administrative and medical watching over the nurse children; the persistence, especially in country districts, of injurious practices and prejudices, kept up by ignorance, respecting the care required by the children, and the adoption of the system of feeding the children too soon by hand.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17s. 4d.; free by post, 19s. 6d.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & CO., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The First Volume, containing upwards of Two Thousand Articles abstracted and compiled by a staff of Fifty Hospital Surgeons and Physicians, is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for the year 1873 are also ready, price 1s. 6d. each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & CO.—Calcutta: THACKER, SPINK & CO.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & CO.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & CO., to Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, OCTOBER 14, 1874.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

PELLIZZARI, TOMMASI, PERRONCITO, COBBOLD, LEWIS AND GIACOMINI ON CYSTICERCI.

Great activity has of late been shown by members of the profession in Italy in reference to parasites, and especially to such of them as are in any way concerned with sanitary matters. Thus Professor G. Pellizzari recently communicated to the Medico-Physical Academy, at Florence, the results of a series of experiments conducted by himself, with the assistance of Dr. Tommasi, in regard to the temperature necessary for the destruction of cysticerci in meat. An account of these experiments is appended to Dr. Tommasi's edition of Dr. Cobbold's *Manual of the Internal Parasites of Animals*.* They were made in view of certain sanitary measures proposed to, and effected by, the Municipal Commission of Florence, the object being to prevent the distribution of measly meat generally, and especially that of swine. Signor Bosi, the superintendent of the public slaughterhouses, granted every facility in his power. According to a previously published memoir by Professor E. Perroncito, it was stated by him that measly meat (*panicultura degli animali*) required a higher temperature than that of boiling-point for the destruction of the bladder-worms in question. In this opinion Signor Bosi shared. According to the original memoir of Perroncito, the title of which is not supplied by Dr. Tommasi, we are told that 'about twenty specimens of cysticerci were collected by the author, and placed in boiling water. After twenty minutes' boiling, not one of the parasites appeared to suffer. The head continued to be drawn into the body, and when the cysticerci had their heads drawn out one by one, they still appeared to possess all the elasticity of living bladder-worms, displaying those movements of extension which are proper to parasites not yet dead. The hooks were observed regularly disposed on the proboscis, where they formed a double crown, the suckers remaining intact.' Perroncito remarked, however, that the cysticerci showed a colouring tendency towards brown, and ingenuously added that 'with the aid of two needles it became easy to lacerate the body of the cysticercus, which appeared to be swollen, and possessed of diminished cohesion of its parts.' It was evident to all eyes, remarked Professor Pellizzari, that these statements involved clear contradictions. Yet again, at page 28 of the memoir, as quoted by Tommasi, Dr. Perroncito says: 'During the past winter I introduced some little slices (*fettucce*) of muscle-flesh (8 to 10 in. in thickness), infested with

cysticerci into a vessel (*cassolina*) containing fat at the temperature of 190 to 200° Cent. (374 to 400° Fahr.) At the expiration of ten or fifteen minutes the slices of meat were fried, and the cysticerci lying at the surface had acquired a light brownish colour, as if they were toasted. By breaking up the slices one could still see the small reddish muscular bundles, whilst the cysticerci in the middle remained entire and well-preserved. Their heads displayed the hooks and suckers regularly distributed.' It is certainly singular, as Pellizzari observes, that these cysticerci, having been thoroughly fried and roasted, should still remain alive and in their normal state; but the ultimate conclusion at which Perroncito arrives is still more startling, and one which, if it were true, would not fail to create a considerable stir amongst our officers of health. On reviewing the whole matter he says 'It appears to me that the melted fat alone of measled hogs (*maiali grandinosi*) should be utilised, and I am pleased to reckon the illustrious Gerlach and all other distinguished practitioners to be of the same opinion. Permit me, therefore, being well satisfied also with the results of many other experiments, once more to advance the conclusion that, if it is not certain that the cysticerci die at from 80 to 100° Centigrade (176 to 212° Fahr.), we are quite sure that they dry up and become completely mummified at 125, 130, and 150° Cent. (257, 268, and 302° Fahr.), temperatures which we could easily produce by means of a properly constructed apparatus.'

After remarking upon the serious nature of the conclusion which Perroncito seeks to establish, Professor Pellizzari makes further use of quotations which bear upon the question as to whether the quality of the vessels in which the fat of diseased hogs is melted down may not largely affect the degree of high temperature sought to be obtained (in view of a perfect destruction of the cysticerci). Perroncito repeatedly witnessed the operations of pork-butchers; and when portions of meat were introduced, with water, into the cauldrons, he always saw that the temperature 'was maintained between 97° and 98° Centigrade.' However, this part of the question may be dismissed in a very few words, since Perroncito himself finally allows that 'the different composition of the vessels cannot elevate the temperature of the fat by many degrees.'

With the praiseworthy intention of either verifying or refuting these conclusions, Pellizzari, with the approval of Bosi and with the assistance of Tommasi, instituted a fresh series of experiments at a private laboratory (*Gabinetto d' Anatomia Patologica*). The details of these experiments are exceedingly interesting; but as the record of them occupy several pages of the appendix already referred to, we must content ourselves with a general statement of the results obtained. To be brief, Professor Pellizzari found that cysticerci, so far from acquiring a temperature of upwards of 100° Cent. for their destruction, die at a temperature of 60° Centigrade. (140° Fahr.) He had, it appears, previously taken the initiative in recommending certain measures to the Florentine municipality, in view of protecting the public health, and he had now the satisfaction of more than confirming the wisdom of these sanitary precautions. The precise nature of these measures of prevention are then stated at some length. In excessively measled animals, the fat is removed and boiled in suitable caul-

* Appendice. Parassiti interni degli Animali Domestici. Trad. dall' Inglese ed Annotato col permesso dell' Autore, dal Dott. Tommaso Tommasi. Firenze, &c. 1874.

drons, and has potash mixed with it to render it useful for industrial purposes. By these various measures the entire animal is utilised, and with such precautions there seems very little chance for the measles of the hog to arrive at the tænioid or sexually mature condition.

In the next part of his communication, Pellizzari touches upon the question of measles in beef, referring especially to the experimental labours of Leuckart and Cobbold. Quoting from the Italian edition of the *Manual of the Parasites of Domestic Animals*, by the last named authority, he finds additional support to the view already advocated and thus is led to pronounce upon the propositions of Dr. Perroncito as of no value whatever. 'But how is it,' he adds, 'that notwithstanding that so low a temperature suffices to kill these cysticeri, yet cases of tænia are continually occurring?' The answer to this question will appear in the sequel.

(To be continued.)

THE HERMIT OF RED-COATS' GREEN.

Dr. Daniel Hack Tuke has published in the *Journal of Mental Science* for October, a very interesting account of this eccentric person—whom Dickens made celebrated as Mr. Mopes. The detailed report of his life, history, and character, leaves no doubt of his insanity, while it gives room to regret that his person and property were not placed under legal protection. Of handsome means and good education, he displayed while young the utmost eccentricity and violent self-will. At his mother's death, he kept her body in the house from October, 1849, to January, 1850, and only allowed its interment when his brother, as executor, insisted. He began from this time his life as a hermit. Before this, his eccentricity had been most marked. He would occasionally hunt; 'when he did so, he rode either with his shirt outside, or in a nankeen suit, barefooted and wearing a small cap, or bareheaded, his long, uncut hair streaming in the wind, presenting altogether a very remarkable appearance; the more so, as he rode on a high-peaked saddle, a string passing round him being fastened to the peaks in front and behind, and a rope for his bridle and stirrups. . . . At other times he would ride in a carriage, his hair done up in curl-papers.' From the year 1849 he began his life of isolation, living in the same house to his death.

'As you approached, it told a tale respecting the occupant. Every window, and even the doors, were carefully barricaded, and the house was allowed to go to rack and ruin; so likewise was the garden—

"The beds were all untouched by hand or tool;
No footstep marked the damp and mossy gravel;
Each walk as green as is the mantled pool,
For want of human travel."

In the beautiful park-like meadow which surrounded the house stood a blasted oak—fit emblem of the blighted life of its owner. Another tree which had fallen across the garden walk had only been cleared away sufficiently to allow of a passage along the path leading to the house.

'When,' says Dr. Tuke, 'I paid the hermit a visit some years ago, I went up to the window of what had been the kitchen, the glass and casement of which had long disappeared, the strong upright iron bars alone remaining. Here the possessor of ample means, and a man of at least fair education, lived

day and night. He appeared to emerge from a bed of ashes (he had not slept in a bed for many years); and I observed that, when his room was entered after his death, the floor was found to be a couple of feet or more deep with the cinders which had accumulated. A farmer informs me he removed after his death fourteen cart-loads from the house and around it. On my appearing at the window he came forward, and entered (though with apparent reluctance) into conversation, his countenance being marked by an expression of suspicion. His aspect was quite in keeping with his abode. Unwashed for many years, his skin was not in a desirable condition, the white of his eyes contrasting strangely with the rest of his person. Clothes he had none; only a dirty blanket loosely thrown over him. For long his hair had been a stranger to the scissors or razor, and its profusion might have been magnificent, but that it was matted with dirt. The photograph of a sketch which was made of him as he sometimes appeared at the window, will convey a clearer idea of his appearance than any description I can give. He was about five feet six inches in height, rather muscular, his hair and eyes dark, the latter prominent, and his complexion pale. His forehead appeared to be well developed. In the room were a fire, an old table, and numerous bottles. There was also a chair, and I understand that a basket was suspended from the ceiling, in which he kept his food, to protect it from the rats which abounded in his establishment. You will remember that Dickens says he saw one run across his face as he lay asleep.

'He spoke to me in a low, rather plaintive tone of voice, and gave me the impression that he was labouring under a certain amount of fear or apprehension. Part of his conversation, which otherwise was perfectly rational, conveyed the same impression. He intimated that his relations were against him, and I understood him to give this as a reason why his house was barricaded. So far as I could make out through his prison-like bars, he was labouring under a partial insanity—a monomania of suspicion or persecution.'

He would not attach his name to any deed or paper bearing her Majesty's stamp, the reason assigned being that she was not the rightful heir to the throne. Nothing could induce him to use either a postage or receipt stamp, lest he should seem to admit the Queen's supremacy. With curious inconsistency, he had no scruple against making use of the coin bearing her image. From the same objection he would not cash his dividend warrants, which remained in his house, forming an accumulation of very dirty papers. He had the characteristic fear of poison; his diet was bread and cheese, red herrings, milk, and gin. For some years he had given up milk, suspecting that poison had been put into it. The great novelist, and others more accustomed to deal with insanity than he, did not consider that Mr. Lucas was a person whom the law could properly take under its guardianship as a person of unsound mind. We cannot help thinking that it would have been far kinder and more reasonable to recognise his obvious imbecilities, delusions, and miserable alterations of opinion and conduct as constituting him a lunatic, requiring proper care and decent attendance. Mr. Mopes is a picturesque monster enough; Mr. Lucas, from whom he was drawn, was, we think, a neglected lunatic. If the lunacy laws were always as loosely interpreted, we

should have a large crop of such hermits, and neither society nor the individuals concerned would be the better for the license to hoard their pence, neglect their property, wallow in filth, and flout the laws of decency and sense.

A CASE OF LIGATURE OF THE COMMON ILIAC ARTERY; WITH REMARKS. BY DR. A. M. BARBOSA, OF LISBON.

(Continued from page 627.)

3. *The Operation: with Considerations on the Anatomy of the Parts.*—The evening before the operation, I prescribed for the patient forty grammes (nearly $1\frac{1}{2}$ ounce) of castor oil, in order to evacuate the gases and other contents of the bowels, and thus reduce the bulk of the descending colon, the sigmoid flexure, and the rectum. This would render the abdomen more flaccid, and facilitate the manual operations, especially in an individual whose abdomen was remarkably large.

Along with bistouries, forceps, tenacula, etc., I brought to the operation two instruments which I had made especially for this case; I derived great advantage from them during the operation, and believe that they may be useful in ovariectomy. These instruments were retractors, formed each of an inflexible plate of polished white metal, bent in the form of an Italic S at the end; they were intended to separate widely the edges of the wound, and expose the vessel to be tied. They are 29 centimètres (about $11\frac{1}{2}$ inches) long; one is 5 centimètres and the other 2 $\frac{1}{2}$ centimètres wide.

[Here follows an elaborate consideration of the anatomical relations of the vessels and their possible variations. The author makes copious reference to Mr. Quain's work on the *Anatomy of the Arteries*.]

Taking into consideration the anatomical facts, I proposed to take the following precautions: 1. Not to injure, or to injure as little as possible, the arteries which would have to take part in the re-establishment of the circulation after its interruption by the ligature of the external or of the common iliac, and which lay in the region where the operation would have to be performed (the epigastric, circumflex iliac, and abdominal subcutaneous arteries); 2. Not to injure the peritoneum, but to strip it off carefully from the psoas and iliacus muscles and the iliac vessels; 3. To avoid wounding or including in the ligature the spermatic vessels, the ureter, and the satellite vein; 4. To expose as far as possible the artery to be tied, without stripping off the cellular sheath for more than one centimètre or a little more, so as to insure the probability of solid obliteration; 5. To use for ligature a cord that was not too fine, so as to avoid dividing the external coat as well as the middle and external ones in an individual sixty years old, with a spontaneous aneurism, and whose arteries were very probably in a state of fatty or atheromatous degeneration; 6. To make the incision at first with a view to the ligature of the external iliac artery if this vessel should be found in a favourable condition, and to prolong it upwards and tie the common iliac in case it should be found impossible to operate with advantage on the first-named vessel.

The patient being laid on his back, with his head and shoulders raised by pillows, the edge of the bed was placed opposite the window of a well-lighted amphitheatre. Chloroform was administered by a fifth year's student, Senhor Feijão, who also watched

the pulse and respiration. Another pupil, standing at the patient's left, gave me the instruments in the order in which I had previously arranged them on an adjacent table. Another, standing to the right of the patient, held the sponges to remove the blood from the wound, and a retractor to draw aside the edges when necessary.

The patient having been anæsthetised, I made in the lower part of the anterior abdominal wall, on the left side, a curved incision eight or nine centimètres (three to three and a half inches) long, commencing a centimètre outside the middle of Poupart's ligament, so as to avoid the abdominal subcutaneous and epigastric arteries, and carrying it upwards to a point five centimètres on the inner side of the anterior superior spine of the ilium. The first half of this incision was parallel to Poupart's ligament, and the second formed a curve with the convexity outwards. The skin and superficial fascia having been cut through, I divided the aponeurosis of the obliquus on a director. I then, by means of the director and my fingers, detached the lower border of the obliquus internus from the crural arch, and divided upwards with a probe-pointed bistoury, on a director, the fleshy fibres of this muscle. In the same manner, and with the same precautions, I divided the transversalis and its fascia. The epigastric and circumflex iliac arteries, as well as the superficial epigastric—all of importance for the re-establishment of the circulation—were thus avoided. Having thus reached the loose connective tissue, which at this part unites the peritoneum with the fascia transversalis, I detached it by means of the fingers, upwards and inwards.

I then ascertained that the aneurismal tumour occupied the entire iliac fossa, from which I stripped the peritoneum as far as the inner border of the psoas, without succeeding in reaching the external iliac artery. It therefore became necessary to extend the incision in the direction of the common iliac, in order to tie that vessel. The upper extremity of the incision in the skin was enlarged four centimètres upwards, perpendicularly to the crural arch, as far as a point three centimètres to the left of the umbilicus, and four or five centimètres above the anterior superior spine of the ilium, or at the level of the highest part of the iliac crest. The muscular fibres of the obliquus internus and transversalis were carefully divided in the same direction. The peritoneum was stripped off by means of the fingers, upwards and inwards, the spermatic vessels and ureter being raised with it. With the larger end of the metallic retractor, the peritoneum and the whole inner side of the wound were drawn towards the middle line and upwards. At the bottom, the common iliac artery was exposed, pulsating, and of very large size. Having carefully separated the artery from the vein which lay to its inner side by means of a probe, I passed a large and strong ligature under it from within outwards, by means of a Birg's needle, and tied it, bringing out the two ends of the ligature through the most dependent part of the wound. The wound bled but little, and was quite clean.

I then applied three points of suture to the upper half, and one to the lower, leaving open a small intermediate portion at the part most dependent in the position of the patient. Strips of adhesive plaster between the sutures, pieces of dry charpie, a compress, and a bandage, complete the dressing.

The pulsation and bruit in the tumour ceased

immediately on the application of the ligature, as they had done when I compressed the artery with my finger before tying it.

The patient was replaced in his bed, with the trunk in a slightly elevated position, and the whole limb wrapped in a woollen covering, and was taken back from the operating theatre to the infirmary.

4. *Progress of the Patient after the Operation.*—Half an hour before the operation, the pulse was 80, and the temperature in the axilla 38° Cent. (100.4° Fahr.); a short time after the operation, the pulse rose to 112, and the temperature fell to 37.2° Cent. (98.96° Fahr.) The left limb (on the side operated on) was a little colder to the touch than the other. The constant and more or less intense pains in the limb, which extended from the groin and adjacent parts to the inner side of the leg, had ceased. He was ordered to have beef-tea every four hours.

At 6 P.M. the pulse was 128; the temperature in the axilla 39.6° Cent. (103.28° Fahr.), and in the left popliteal space 36° Cent. (96.8° Fahr.) The whole limb was normally warm. The patient had some cough, which appeared to have been excited by the chloroform. At midnight the pulse was 136, and the temperature in the axilla and popliteal space nearly as before. The limb was less swollen.

February 8, 8 A.M. The patient had slept three hours, with interruptions. The limb felt normally warm. There was no meteorism nor increased sensibility in the abdomen, either spontaneous or on pressure. The compresses, which had become tinged with reddish serum, were removed, and fresh ones applied. The wound had a healthy aspect. 8 P.M. The dry cough was more frequent. The patient was ordered a granule of Homolle's digitaline (.0075 grain) every four hours, and a spoonful of syrup of morphia in two of tea when the cough was troublesome.

February 9, 8 A.M. He had slept little; the cough was less. The limb was less oedematous, and of normal warmth. The wound was suppurating abundantly, and the dressings were changed twice a day. He was ordered to have strong beef-tea, with toast and marmalade *ad libitum*. At midday the pulse was very weak. The urine was less high-coloured than it had been, and in better quantity; it contained no albumen. The cough was less intense; the tongue was coated and dry, there was sore throat. The digitaline, of which the patient had taken only three granules, was discontinued.

February 10, 9 A.M. The pulse was less weak, the tongue more furred and dry. The urine was scanty, high coloured, with an abundant deposit of lithates, but no albumen. There was general prostration, which had not previously existed. There was an abundant discharge of slightly fetid pus; the surface of the wound, as far as it could be seen, was covered with a thin dull grey false membrane. The abdomen was somewhat tender on pressure, but only in the neighbourhood of the wound; there was slight meteorism. The sutures were removed from the lips of the wound, which were not united. The wound was dressed three times a day, the discharge from it being facilitated by the position of the patient. Six decigrammes (9½ grains) of sulphate of quinine were ordered to be given in three doses, with sulphuric lemonade. For diet, strong beef-tea with some rice was given, and a tablespoonful of port wine every four hours. At 8 P.M. the pulse presented an alternation of weak and strong beats.

February 11, 8 A.M. The patient had slept only a

little, for very short periods, and felt very weak. The pulse was regular, but weak. The lips of the wound were much separated; the suppuration was more abundant, and fetid; the whole surface of the wound was covered with a grey, very thick, adherent false membrane. There was increased tenderness on pressure near the wound, and more meteorism. The wound was ordered to be dressed with dry charpie four times in the day, having been previously washed with a warm carbolic-acid lotion (one part in 500 of water). The prescriptions of the previous day were continued; and half an ounce of port wine was ordered to be given every three hours.

February 12, 10 A.M. Pulse weak. The tongue was covered with a very thick yellowish fur; the patient was very thirsty; the urine was scanty and deposited a copious sediment; he had had a semifluid evacuation. The prescriptions were repeated, and he was allowed a drink of *capillaire* syrup and water *ad libitum*. 8 P.M. Pulse 160, very small. The treatment was continued, and a granule of digitaline was ordered to be given every six hours.

February 13, 9 A.M. Pulse very small, 128. His countenance expressed apathy and indifference; there was increased prostration; the tongue was drier; he had a copious semifluid stool. There was less suppuration, but the discharge from the wound was ichorous and fetid. The surface of the wound, even at the deepest parts, was covered with a thick, dirty, closely coherent membrane. The wound was ordered to be dressed four times in the day with dry charpie, having been previously washed with tepid carbolic-acid solution (1 part in 300); 15 grains of sulphate of quinine were ordered to be given in six doses, and two granules of digitaline, one in the morning, the other in the evening. The diet consisted of strong beef-tea, with 20 grammes of port wine every two hours. The patient was removed from the ward to a house in the hospital enclosure, near the botanical garden, a locality well provided with light and air, and exposed to the sun.

February 14, 8 A.M.—His extremities, nose, and ears, were cold; he was extremely weak; the pulse was very small, almost imperceptible, 140. He died at 2 P.M., without having manifested any delirium or signs of suffering.

[Dr. Barbosa gives charts of the pulse and of the temperature in the axilla, and in the right and left popliteal spaces. The accompanying table (*see* next page), compiled from the daily reports of the case, shows the variations observed.]

5. *Necropsy.*—The necropsy was made twenty-four hours after death. It was not performed with so much care as was desirable, as the patient's family were in haste to inter the body, and manifested great opposition to an examination.

The operation-wound was gaping, and the whole surface was thickly covered with a very adherent thick false membrane, consisting of a pulpy, dirty grey, fetid substance, resembling in appearance that observed in sloughing hospital gangrene. On opening the abdomen, the peritoneal cavity was found to be completely closed, the peritoneum not having been wounded in the operation. The large muscles of the left half of the abdominal wall, and the ilio-psoas of the same side, with the corresponding connective tissue, were infiltrated with altered pus, which gave them a dirty lead colour. The peritoneum on the left side presented all the signs of acute suppurative inflammation, from the part co

responding to the wound as far as the middle line. Recent adhesions, formed by fibrino-purulent false membranes, between the abdominal wall to the left of the linea alba and the corresponding intestines, limited the area of inflammation; the right half of the abdominal cavity, both peritoneum and intestines, being in a normal condition. The spleen, which was not very large, was softened, and covered with concentric layers of ashy yellow false membrane, infiltrated with pus. The liver was much congested, and its surface presented numerous distinct spots of a dark-red colour, like ecchymoses; they varied from one to three centimètres in their greatest diameter, had an irregular outline, and did not pass more than two or three millimètres into the parenchyma of the organ. The signs of suppurative inflammation of the peritoneum reached as high as the left hypochondrium, and were continued in the pleura of the corresponding side, in which there was an effusion of about 300 grammes (about ten-and-a-half ounces) of yellow turbid fluid, containing fibrino-purulent flocculi; there were also deposits of the same character in the costal and pulmonary pleura. The left lung was compressed by false membranes, and was much congested with dark-coloured blood. The right lung was healthy; but the pleura, both pulmonary and costal, was covered in various parts with thin, slightly adherent, recent false membranes; these were fibrinous only, and were easily removed. The heart and great vessels presented no alterations appreciable to the unaided eye. The blood contained in them was dark, grumous, and semifluid.

The aneurismal tumour occupied the whole of the left iliac fossa. Its superior limit was 4 centimètres (about 1½ inches) above and to the outer side of the point where the common iliac artery had been tied, and 1 centimètre below the origin of this vessel. Externally, it touched the crista ili, and internally the brim of the pelvis. The aneurism extended down the inner side of the thigh for 13 centimètres (5 inches), to below the trochanter minor, under the crural arch and fascia lata. The large aneurismal sac was formed in the three upper fourths of the external or cellular tunic of the artery, extremely distended and hypertrophied, with the connective tissue in the neighbourhood thickened by the chronic inflammation to which it was subjected during the development and growth of the tumour. Its thickness, including the more adherent layers of fibrin,

varied from 2 to 10 centimètres (0·8 to 4 inch). At some points of this part of the sac, Dr. Camara Cabral and I discovered by microscopic examination vestiges of the inner and muscular coats of the artery, in the form of elastic and muscular fibres in a state of granular and fatty degeneration, as well as granules and masses of hæmatin. In the lower fourth of the aneurism, the sac appeared to consist solely of connective tissue formed into a fibrous membrane from 2 to 4 centimètres thick. The communication between the artery and aneurismal sac was established by means of an elliptical opening, with smooth rounded edges, measuring twenty millimètres (about four-fifths of an inch) in its greatest diameter, which was in the direction of the axis of the vessel, and ten millimètres in the opposite direction. The lower part of this opening was scarcely a centimètre distant from the origin of the deep femoral artery; and its upper part was eight and-a-half centimètres from the origin of the external iliac. The aneurismal sac was full of coagula; some fibrinous, in the form of laminæ more or less irregularly deposited; the most external being adherent to the inner surface of the sac, and more or less combined with it, and the greater part being dark, soft and diffuent. The blood having been removed, the aneurismal sac was macerated for some days; it was found to be twenty-seven centimètres (ten and a half inches) in circumference, and three and a half inches in its transverse diameter. From the origin of communication with the femoral artery to its upper limit, it measured nearly six inches; and from the same point to its lower limb, four inches and three quarters. The femoral artery, above and below the surface, was in immediate contact with the sac, and was flattened and compressed by it. The external iliac artery, which did not form part of the aneurism, was, however closely adherent to and flattened by the sac, with the exception of two centimètres at the upper end.

The common iliac artery had been tied five centimètres (nearly two inches) from its origin, and a centimètre above its division into the external and internal iliacs. The interior of the artery, from the point of ligature to its origin from the aorta, was occupied by a cylindrical coagulum, not deprived of colour, consistent, and fibrinous; in fact, as was observed, by a thrombus of black soft blood, in which it was difficult to find a small fragment of fibrillated fibrin. This thrombus had no adhesions to the corresponding surface of the artery; on the contrary, it was very easily separated. At the point of ligature, the continuity of the inner and middle coats was interrupted all round, their tissue having been broken through by the ligature. The arterial wall of the ligatured part was thus solely formed of the external coat, which had become adherent at its points of contact by means of fibrous connective tissue—a true new formation proceeding from the irritation produced by the ligature. This newly formed tissue occupied an extent of five or six centimètres; it appeared to the unaided eye to be marked with striæ or fasciculi; and, on examining it with the microscope, Señor Amado found it to present all the characters of fasciculated connective tissue.

Anatomical and microscopical examination of the lower part of the aorta, of the common and external iliac arteries, and of the femoral where the aneurismal rupture had taken place, demonstrated the existence of granulo-fatty degeneration in various parts of the

inner coat and of the adjacent layers of the middle coat. In many points even the unaided eye could detect the disease of the arteries, not only by the change of colour and slight tumefaction, but also by the existence of some hard calcareous deposits. In the softer points there were noticed fatty granules and crystals of cholesterine. In the apparently healthy portions, the microscope discovered numerous fat-granules. At some points in the deeper layer of the inner coat of the arteries, colouring matter of the blood was found in the granular form (hæmatin) and in the crystalline form (hæmatoidin).

The blood, when examined under the microscope, did not show any vestiges of lower organisms, bacteria, or any notable change. The exudation from the wound, beyond pus-globules and some changed and granular blood-corpuscles, contained only a few vibriones.

ANATOMY AND PHYSIOLOGY.

MACH ON PHYSICAL EXPERIMENTS ON THE SENSE OF EQUILIBRIUM IN MAN.—‘In travelling along a sharp railway-curve,’ says M. Mach, in a recent paper to the Vienna Academy, ‘the houses and trees often seem to deviate considerably from the vertical, their tops leaning away from the convex side of the curve. On the other hand, one often notices an oblique position of the carriage, and then holds the trees to be vertical. It is known that the rail on the convex side is elevated a little to compensate centrifugal force. But the difference of level can only correspond to one rate of speed. The apparently contradictory facts mentioned are readily explained, if we suppose that one perceives the direction of the vertical, and always considers as vertical the direction of acceleration of the solid parts of the body, resulting from gravity and centrifugal force. If we travel with the speed corresponding to the difference of level of the rails, and to the curvature, we know nothing of the oblique position of the carriage. Then the houses appear oblique. In every other case the carriage seems oblique.’

M. Mach made a number of experiments on the subject; some of which we will briefly describe. The apparatus consisted of a large vertical frame, R, which could be rotated about a vertical axis, A; within it a smaller frame, r, capable of turning round another vertical axis, a, which might be removed to any suitable distance from the first. In the second frame was a chair for the observer, which could be turned about a horizontal axis, a. He could be enclosed in a paper case.

Experiment 1.—The observer, sitting enclosed in the case, his chair was turned back round the axis, a, and he was required to show by a rod the direction he thought vertical. It appears that, as he approached the position of lying on his back, he estimated the divergence from vertical as less than it really was.

Experiment 2.—The observer, sitting upright in the paper case, was rotated about A. He perceived the direction and (roughly) the amount of the turning; but if this were continued uniformly some seconds, the feeling of rotation ceased; and when the frame was left to itself so that it became gradually slower in movement, a feeling of opposite rotation arose. This feeling was strongest if the frame were suddenly stopped, and it continued some seconds.

Thus was perceived, not the angular velocity, but the angular acceleration. An optical phenomenon was also noted. If, after stoppage, the case were suddenly opened, the whole visible space seemed to rotate with its contents; and it was as if it were within a second space, conceived to be quite fixed.

Experiment 3.—The frame was stopped suddenly, and, after one-and-a-half to two seconds, suddenly set going again in the same direction. The feeling of opposite turning, which arose in the interval, disappeared when the motion was resumed.

Experiment 4.—If, in experiment 2, the head were bent forward, and raised after stoppage of the apparatus, the observer, if the rotation had been (say) from right forward then to left, felt as if turning from right upwards to left, and was afraid of falling to the side.

Experiment 5.—In experiment 2, images at rest on the retina seemed as if moving. The idea was suggested that this motion might be neutralised by an opposite one on the retina. A hollow drum was substituted for the paper case, capable of turning about a vertical axis, and lined inside with paper, on which were drawn equidistant vertical lines. As the frame was rotated, the drum moved with it; but on the former being stopped, the latter still went on, with a retarded motion. The observer, within the drum, felt as if it were at rest and himself in so much the faster opposite motion. Thus apparent motion can be compensated with actual.

Experiment 6.—The observer was placed a mètre from A, in nearly vertical position, looking towards A, and rotated (about A). When the angular velocity became constant, the sense of turning ceased, and he only thought himself more on his back than was the case. The direction of resultant acceleration of motion was taken for vertical.

Experiment 7.—The arrangement was the same as in experiment 6, only by turning the frame r about a, the observer was made to look in a direction at right angles to the plane of the axes A and a. When the velocity became constant, he seemed to himself, along with the case, to be constantly inclined to the side, his head inclining away from the axis of rotation. On stoppage, he felt righted again.

Experiment 8.—In the arrangement for experiment 7, a pendulum being hung in the case with a graduated arc, it was observed to diverge 10° to 20° , showing a centrifugal acceleration about one-fifth to one-third the acceleration of gravity. Now, this pendulum was thought vertical during the rotation, while the case and the observer himself seemed inclined.

Experiment 9.—When, in experiment 6, the apparatus was suddenly stopped, the observer seemed to himself for a moment inclined sideways, with his head in the direction of rotation. Each momentary progressive acceleration whose direction did not coincide with the true vertical, momentarily altered the apparent vertical.

Experiment 10.—Suppose a large equal-armed balance, each arm being two mètres in length. The observer was in one scale, and he was balanced with weights in the other. If the balance were set oscillating, the observer underwent an almost purely pendulum motion. With a vertical excursion (from the position of equilibrium) of 15 centimètres, and time of oscillation of the beam 7 seconds, the vertical acceleration was 12 centimètres, or about 0.012 of the acceleration of gravity. The oscillations were

then, for the blindfolded observer, at about the limit of perceptibility. If the excursions were greater, he each time supposed he was sinking, shortly before reaching the highest point, or when at it. And he supposed himself to be rising shortly before he reached the lowest point, or when at it. The formula shows that the acceleration downwards is a maximum at the highest point of the course, and that upwards, at the lowest point. M. Mach infers we are also very sensitive to variations in the acceleration of gravity; and in vertical motions we perceive not the position nor the velocity, but the acceleration.

M. Mach attempts an explanation of the phenomena to the following effect.

Conceive a cavity covered with nerve-endings, in a body B, containing a liquid or solid substance A. The latter will (1), because of gravity, press on one part of the walls more than on the rest, and thereby the position of B relatively to the vertical will be indicated. (2). With any acceleration of B, A will exert a counter acceleration (a counter pressure), which is compounded with the acceleration of gravity; so that both the intensity of the pressure and the place of pressure on the wall of the cavity are changed. And (3) with an angular acceleration of B, A will tend to make an opposite rotation. By 1 and 2 B receives a knowledge of its position and progressive motion; by 3, a knowledge of its turning motion. Now, the vestibule, with the semicircular canals, are such an organ as has been described. It is also probable that for 1 and 2 there are special nerves distinct from those for 3. If we consider the canals, they seem specially fitted for application of the principle of surfaces. For every angular acceleration about the axis perpendicular to the plane of the canal, the contents must exert a rotation-moment in the opposite direction, which the nerves of the ampullæ convey further as indication of this angular acceleration.

If we accept with Müller that the ampullary nerves have the special property of responding to every stimulus with a sensation of turning, we shall find many phenomena observed by Flourens, Golz, and others, reduced to one principle.

We must further suppose that a momentarily acting rotation-movement calls forth a sensation of turning in the opposite direction (of considerable duration), which, however, can soon be extinguished by an opposite rotation-movement.

M. Mach, in concluding his paper, describes some attempts he made to impart a rotation-movement to the contents of the semicircular canals by means of electricity. Like Ritter and Purkyne, he succeeded in sending a battery current from ear to ear. 'On this experiment,' he says, 'I based new hopes. Suppose, in the plane of this paper the north and south poles of a horse-shoe electromagnet, which is under the paper; and, in a horizontal Barlow disc situated between the poles, send a current from the north pole to the south; a rotation begins in the direction of the hands of a watch. If, now, the head, traversed by a current from ear to ear be placed between the poles, the person experiences, at opening and closing of the circuit, a turning jerk (*Ruck*) or shake; but I did not succeed in obtaining a pure phenomenon, probably from want of anatomical local knowledge. I do not doubt, however, that an expert physiologist may obtain good results from this experiment.'

DAVID ON THE PHYSIOLOGICAL ACTION OF APOMORPHIA.—The author describes, in the *Comptes Rendus* of August 24, some experiments made at Geneva on the physiological action of chlorhydrate of apomorphia. The solution, administered to a dog, by subcutaneous injection, in a dose of a half to two milligrammes, produced vomiting in four to six minutes, preceded by very short nausea. For a cat, the emetic dose was much higher; and it seems to vary from one animal to another. Thus thirty-five milligrammes of the preparation was insufficient to produce vomiting in one cat, while another vomited after two milligrammes. For the pigeon, the minimum emetic dose is four milligrammes. Vomiting was produced in man by three to four milligrammes. There was slight uneasiness and vertigo immediately before it. The vomiting came on suddenly, and was renewed three or four times. Recovery soon followed.

M. David treats his results under two heads.

1. *Influence of different agents on the action of chlorhydrate of apomorphia.*—Chloroform, given in resolute dose, retards the action of apomorphia in the dog, till the period of waking. The vomitings are then produced by the same doses as in the normal animal. Chlorhydrate of apomorphia, administered during the period of waking, acts in the same doses and in the same time as on the animal not chloroformed. Chloral injected into the veins suspends entirely the action of apomorphia. Morphia, even in a dose of three centigrammes, in moderately healthy dogs, hinders the action of apomorphia. The employment of apomorphia would thus be useless in the case of acute poisoning by morphia. The author obtained vomiting with a dose of four milligrammes in a man who, habituated to morphia, received about sixteen centigrammes of it daily by subcutaneous injection. In the pigeon and the guinea-pig, the morphinism produced by a dose of two centigrammes does not prevent the physiological action of apomorphia (which will presently be noticed). Section of the vagus nerves, in a dog, with or without chloroform administered, does not in any way modify the action of apomorphia. In an atmosphere surcharged with oxygen, the dog merely vomits under the influence of the same doses and in the same time as when placed in atmospheric air. Asphyxia nearly complete, prolonged during more than a quarter of an hour, has also no influence on the action of chlorhydrate of apomorphia.

2. *Excitant action of apomorphia.*—Chlorhydrate of apomorphia seems to have a special action on the nerve-centres of certain animals, such as the cat, the pigeon, the rabbit, the rat, and the guinea-pig. Cats, after injection of two to thirty-five milligrammes of apomorphia, present, almost immediately, all the symptoms of fear. They shortly escape to a dark corner of the room, take alternately a few steps forwards and a few backwards, and smell the floor, pushing the head quickly forward or to the side. The phenomenon is accompanied with an abundant salivation. This agitation had been attributed by M. Siebert to the nausea before vomiting, but the author agrees with M. Hartnack in rejecting this interpretation. He found that the agitation was also produced when the dose of apomorphia was not sufficient to produce vomiting. And it is not always interrupted by the stage of vomiting. Other emetics (tartar emetic and ipecacuanha), produced vomiting preceded by manifest nausea, but without any

symptom like those which the apomorphia produced.

Rabbits, a few minutes after injection of six to eight milligrammes of apomorphia, rush from one corner to another of their cage, driving against its sides, constantly beating with their hind feet, and emitting slight cries. They start at the least movement made near them. During this time, the respiration is rapid and loud.

The pigeon, after injection of one half to four milligrammes, is agitated, springs, cries, pecks with violence indifferently at spots on the ground, or seeds offered it, pecks also its feathers (as if seized with severe itching), and other pigeons near it. This state may last more than an hour and a half, and is not modified by the regurgitations which take place when the dose is sufficient to produce vomiting (four milligrammes). In two pigeons, from which the brain had been removed, the agitation was not produced. Other emetics (above named) produced nothing at all like what has been described.

Morphia in the dose of one centigramme simply made pigeons drowsy, without giving rise to any agitation.

The rat, with a dose of two to four milligrammes, enters into continual agitation. It is in a state like drunkenness, steadies itself on its legs, and falls backwards, spite of incessant efforts to the contrary. This agitation ceases in an hour or two; but the animal continues giddy for a long time.

The guinea-pig, three or four minutes after injection of a half to twelve milligrammes, becomes very terrified. It shortly begins to gnaw, without interruption, whatever is presented to it—the flag-stone of the floor, the feet of tables, etc. This is sometimes accompanied with copious salivation. The agitation lasts two hours and more, and is very similar to that described above.

ALEX. B. MACDOWALL.

PATHOLOGY.

KLEIN ON THE PATHOLOGY OF ENTERIC FEVER. Dr. E. Klein has for some time past been engaged, at the instance of the Medical Department of the Privy Council, in investigating the morbid anatomy of typhoid fever by means of the microscope. As this inquiry is temporarily suspended, he has communicated an abstract of the results to the *Centralblatt für Medicinischen Wissenschaften*, for Sept. 21 (no. 44), from which we take the following.

1. Sections (previously hardened) of the ileum from persons dying in enteric fever, show that an active (*rege*) absorption of peculiar organisms has previously occurred in the mucous membrane over Peyer's patches, especially in that just surrounding them; and that these are carried thither by the lymphatic vessels and veins of the mucous membrane.

2. The earliest case examined by him (dying seven days after the first occurrence of headache) exhibited peculiar greenish brown, for the most part spherical bodies, which were found within (*in Lumen*) the follicles of Lieberkühn; the size of these was somewhat variable, the largest being two or three times as large as a red blood-disc, whilst the smaller were half or quarter of that size. They lay for the most part massed in groups, presenting an olive-green tint. At the edges of such groups, or

where they lay singly, many sectional outlines were visible—reniform, biscuit-shaped, etc. These minute bodies were also found in the mucous tissue, and appeared to be contained within the lymphoid cells (lymph-corpuscles) of the adenoid tissue. The veins and some of the lymphatic spaces were very rich in these organisms. In the former, they soon proceeded to exhibit a rapid double and quadruple fission, thus splitting off into still more minute, and for the most part greenish yellow, granular micrococci; which combined together in twos, or fours, or in necklace (rosary-like) chains, or even actual zoogloea. The micrococci, moreover, were closely related to a mycelium with branching threads, smooth outline, and a greenish-yellow colour. [These results are similar to those which Dr. Klein communicated to the Royal Society as regards sheep-pox—the account of which is now in the press]. These organisms are not only found close to those Peyer's patches which are moderately swollen, but also in parts of the mucous membrane which only exhibit very slight general swelling, when viewed with the naked eye. The Peyer's patches in such parts exhibit peculiar changes which will be described hereafter. In addition to these organisms, one finds masses (*Ballen*) of greenish-yellow micrococci pervading the mucous membrane from the free surface, through the epithelium, and in the tissue itself, especially in Lieberkühn's follicles, and passing from these again into the lymphatic canals. [As Dr. Klein promises a continuation, any comments would be premature.—*Rep.*]

W. BATHURST WOODMAN, M.D.

MEDICINE.

JACKSON ON HEMIPLEGIA.—In the papers mentioned in the note,* Dr. Hughlings Jackson reviews the whole subject of hemiplegia, and the lesions of the corpus striatum which induce epilepsy and chorea, with special reference to the question of recovery from severe injuries of the great motor ganglia of the central nervous system. On the latter point, in particular, his views have been much misunderstood, and consequently misrepresented. It may, therefore, be as well to set forth as clearly and succinctly as possible, what Dr. Jackson really does teach and write upon these interesting topics. This is, perhaps, still more seasonable, as a recent paper on 'Brain-Injuries,' by Dr. Henry Day, of Stafford, in the last volume of the *St. Andrew's Medical Graduates' Transactions* (vol. vi. pp. 210-228) seems, if we do not mistake the author's meaning, to point in a somewhat backward direction, and to ignore almost completely the positive results of clinical experience, and *post mortem* examinations, in favour of some apparently 'glaring instances' of

* 'On a Case of Recovery from Hemiplegia.' By J. Hughlings Jackson, M.D., F.R.C.P., Lond., *Transactions of the St. Andrew's Medical Graduates' Association*, vol. vi. (for 1872 and 1873) pp. 60-68. Idem.: *The Lancet*, 'Mirror of Hospital Practice.' May 2, 1874, p. 618.

'Clinical Lecture on a Case of Hemiplegia.' By J. Hughlings Jackson, M.D., &c. Reprinted from the *British Medical Journal* for July 18 and 25, 1874.

See also *Medical Times and Gazette*, December 21, 1867; *Medical Mirror*, September and October, 1868; and 'A Study of Convulsions,' by the same author, in the *Transactions of the St. Andrew's Medical Graduates' Association*, vol. iii.

exceptionally severe injuries to the brain, which were followed by but slight and apparently insufficient symptoms. It is possible that some of the opponents of all attempts to localise nervous actions in definite regions of the brain are swayed by conscientious motives, which we must respect. They fear lest 'giving a local habitation and a name' to special functions of the nervous system should end in a crass materialism. In this we think they err, for surely an instrument is no less an instrument, merely because it is complex; and if we reason from analogy, we would say that the more perfect and the more complex the instrument, the more individualised and intercorrelated must be the separate parts and portions of the mechanism. A devout physiologist of robust mind need scarcely be more shocked at discovering that the brain is divided into regions of different properties and powers, than a devout astronomer is scandalised or disturbed by the resolution of nebulae into distinct worlds, and systems of worlds. The wonder and reverent adoration of the latter would in all probability be shared by the former, so soon as he fully comprehended the perfection and complexity, yet withal real simplicity of the mechanism of thought. Our present business, however, is not with the ultimate tendencies of this or that system of psychology, but a brief review of the published teachings of Dr. Hughlings Jackson on the subjects named above.

The first thing that strikes one on comparing the clinical lecture which stands third in the list with the best teachings of our text books, or even with such good stuff as Dr. Todd's clinical lectures on the same subject, is the great breadth of Dr. Jackson's views. He teaches the student emphatically that hemiplegia, chorea, and convulsions, whether 'epileptic' or others, are but symptoms; that the 'case' which presents such and such symptoms is to be studied as a whole. Listen, he says, to his heart and lungs; examine his arteries, use the ophthalmoscope, test his urine, inquire into his history, personal and relative, and do not be content with merely observing and analysing, however minutely, his special nervous symptoms. Although these may not be the exact words, they express most clearly not only Dr. Jackson's teaching, but his practice. At page 1 of this lecture, he writes: 'Do not take a nervous view of nervous diseases. An examination of the patient altogether, and a careful inquiry into his individual and family history, are the things of most importance. The patient's specially nervous symptoms, such, for example, as aphasia and hemiplegia are, from a medical point of view, very often of less consequence than his general clinical state.' It is very interesting to note the stress Dr. Jackson lays upon arterial lesions. 'Most nervous symptoms are not directly of nervous origin. The most important and most common of them are of arterial origin; an artery bursts, and the escaped blood tears up a nervous centre; or an artery becomes blocked up, and a nervous centre softens. Nervous organs very often indeed suffer because their arteries are faulty. . . . These considerations are not to be lost sight of in the consideration of hereditary, as we shall see when we come to speak under the head of Softening of the Brain.'—[*Clinical Lecture*, p. 1.]

In the clinical lecture before us, Dr. Jackson speaks chiefly of the hemiplegia resulting from damage to either the corpus striatum or optic thalamus; in fact, 'the common form of hemiplegia.' 'It depends on destruction of the corpus striatum or optic thalamus.

Observe the manner of statement. It is not scientifically exact to speak of it as a symptom of softening, or of cerebral hæmorrhage, or of tumour; for it is a symptom of destruction of the corpus striatum by any pathological process whatever. I should say "destruction of function," because, although in most cases there is actual breaking up of nerve-fibres and cells, yet in one clinical variety of hemiplegia there is only a temporary exhaustion of the nerve-fibres and cells of the corpus striatum. This is the epileptic hemiplegia of Dr. Todd. The following is my speculation as to its mode of causation. There is in the convulsion a strong discharge of grey matter of convolutions through the corpus striatum to the muscles convulsed. If the discharge be excessive, the corpus striatum is left temporarily *hors de combat*; its nerve-fibres and cells are paralysed in the same way, I suppose, as a nerve can be experimentally paralysed by excessive artificial stimulation.' In a foot-note Dr. Jackson explains epileptic mania on the same principle [*Ibid.* p. 3]. He says strongly, 'Slight and transitory palsy may depend on permanent, although limited, destruction by a very small clot, or softening from plugging of a very small artery. I shall afterwards prove to you that patients recover from hemiplegia, notwithstanding that the paralyzing lesion is not restored.' He believes 'that recovery is to be explained on the principle of compensation. The structure of a nervous organ is, he believes, such that each part of it represents slightly (although such part in some special manner) what the whole organ represents in greater degree.' For example, Dr. Jackson thinks that each part of the corpus striatum represents the face, arm, and leg—that, so to speak, the corpus striatum is a mass of little corpora striata. Let us try to illustrate this, although imperfectly, by analogies and symbols. Let us suppose a note on a trichord piano to be damaged. As long as one, or still more two, of the wire-strings were unbroken, the damage is reparable by simple tuning, and the removal of the broken wire. It is only when all three are destroyed that total loss of the note results—irremediable, except by new structure. Or say the corpus striatum represents, in each part, face, arm, and leg, which we will represent by letters: then the individualised functions may be represented by letters of different type, thus:—

| | | |
|------------------------------------|---|----------|
| 1st, or lower segment . . . | = | l. a. f. |
| 2nd, or intermediate segment . . . | = | a. f. l. |
| 3rd, or highest segment . . . | = | F. A. L. |

For these illustrations Dr. Jackson is not responsible. The following extract from the *Medical Times and Gazette*, of Dec. 21, 1867, quoted again in the *St. Andrew's Medical Graduates' Transactions*, vol. vi. pp. 60-61, puts this still more clearly.

'There is no doubt that a large part of one cerebral hemisphere may be destroyed without any permanent mental effect. It is equally certain that a part of the corpus striatum may be destroyed without any permanent hemiplegia. But no one denies that the hemisphere is the chief seat of the mind, and that through the corpus striatum the rest of the nervous system acts on the limbs. In incomplete hemiplegia—to limit the illustration to the arm—there is not palsy of part of the arm, but partial paralysis of the arm (*vide infra*). So it seems that each movement of the arm is represented in each part of the corpus striatum, or conversely, that each part of the corpus striatum represents the movements of the limbs as a whole. In complete hemiplegia

the arm cannot be moved in any way, except by swinging it from the shoulder; and in incomplete hemiplegia the fault is not so much that some one or more motions cannot be performed at all, the rest of the arm being good, but that although all the movements are to be done, they are all badly done. And when the destruction of nerve-tissue is slight in extent, there need be no permanent defect in any manner of movement. Applying this principle to the brain, we may understand how it is that there may be a large abscess in one cerebral hemisphere, and yet no obvious mental defect. Or, to take with arbitrariness a special series of motor and sensory processes, we see how it happens that disease of the fore part of the anterior lobe, of the posterior lobe, and of the hemisphere above the lateral ventricle, need not produce any defect of the psychophysical processes which constitute the phenomena of language. Just as in the arm nervous system, there is a gradually increasing complexity, from the delivery of nerves to muscles, through interweaving of nerves in the nerve-trunks, to an interrelation so great in the corpus striatum, that damage to a small part of this organ weakens the whole of the limbs, and yet destroys no single movement—so we may fairly infer that, continued from the corpus striatum, deeper in brain—further in mind—are still more complex arrangements of motor processes, reaching a minute degree of interrelation and a vast width of association with the complex motives—the sensation aspect of mind—of the hemisphere, and becoming at length so complete, that a quantity of brain may be destroyed without any special mental defect resulting [? being discoverable].

Dr. Jackson cannot see the force of the general objection to his embolic view of chorea, that the patients recover, sometimes rapidly. He says—‘The fact I have always admitted, but I could never see that the objection was the fatal one it was assumed to be. I have made *post mortem* examinations, showing that recovery had occurred from paralysis due to far grosser cerebral lesions than I or anybody else ever supposed to exist in chorea.’ ‘Let the state of the corpus striatum be carefully considered. There can be no doubt that there are cases of hemichorea exactly like cases of that form of hemiplegia which results from disease in the corpus striatum—like them in that the region affected is the same (face, arm, and leg), is of course meant. It is really far simpler to study first the symptoms of hemiplegia, and next those of chorea and convulsions. The hemiplegia is to be looked on as a sort of experiment, telling us what movements are represented in the corpus striatum and its region. If in another case we find activity of those very parts which are paralysed from a clot in the corpus striatum, what is the inference?’ Dr. Jackson’s views as to the seat and nature of chorea, are well put by Dr. Tuckwell (of Oxford) in the fifth volume of the *St. Bartholomew’s Hospital Reports*—to which we must refer. Some criticisms and Dr. Jackson’s answers to them will be found in the *Obstetrical Society’s Transactions*, (vol. x. p. 147 *et seq.*) The first case of recovery is one of a man aged twenty-one, who had complete left hemiplegia of the usual type, without either cardiac disease or albuminuria. He died in a bath twenty-one months afterwards, but it is not clear whether suicidally or not. Nearly the outer half of the corpus striatum was destroyed. In the second case (*Lancet* May 2, 1874), there was no necropsy, but the woman recovered in three weeks. The

diagnosis made was syphilitic embolism. As regards the gravity of paralysing lesions, Dr. Hughlings Jackson remarks (foot note to Clinical Lecture, p. 11 and elsewhere), that ‘the word grave includes two factors—size of lesion (quantity of nerve-tissue destroyed), and suddenness of lesion (rapidity of destruction). The element of suddenness is a very important one. As Prévost remarks, the deviations mentioned in the text usually accompany “brusque” lesions. Reference is made here to lateral deviations of the eyes and head.’

In a clinical point of view, Dr. Jackson makes three degrees of hemiplegia. The first kind is with slight facial paralysis of the same side, chiefly of the lower two-thirds of the face—the tongue is little affected, and its paralysis does not affect its nutrition. Dr. Jackson thinks that defective articulation of ‘labials’ is due chiefly, if not entirely, to the palate—a statement which, however true in some cases, appears to us in direct opposition to the facts observed in some cases of general paralysis. The second degree of hemiplegia involves some of the trunk-muscles also. To save space, we copy Dr. Jackson’s description—the hemiplegia being supposed to be dextral. ‘1. The head turns to the left. 2. Both eyes turn to the left. 3. The muscles of the chest and belly are weakened on the right. 4. The muscles passing from the trunk to the right limbs are paralysed. 5. The face is paralysed on the right side. 6. The tongue, on protrusion, turns to the right. 7. The right leg is paralysed. 8. The right arm is paralysed.’ The third kind is one of universal powerlessness, paralysis of both sides of the body, or as we may say, there is complete hemiplegia plus paralysis of the other side of the body—but hemiplegic inasmuch as the clot or other lesion is only one-sided, but always severe—a condition, as Dr. Jackson justly remarks, very difficult to be distinguished from opium-poisoning in some cases.

[We feel tempted to quote largely from all these papers of Dr. Jackson’s, but space does not permit. Enough has been said to show that his reasoning is justified, at least to a very large extent, by known facts. It is no longer possible to sneer at this sort of teaching as transcendental. All our best clinical teaching is and must be of this kind. Nature is not to be bound down by our narrow nosologies, and the cramped notions of our text-books. Yet amidst all the apparent confusion and disorder of disease, there is a method, a divine cosmos, which is discoverable only by the most painstaking observation on the one hand, and a logical use of the imagination on the other. Neither singly can suffice.—*Rep.*]

W. BATHURST WOODMAN, M.D.

WESTPHAL AND BERNHARDT ON CERTAIN HITHERTO UNRECOGNISED MOVEMENTS OF THE EXTREMITIES IN HEMIPLEGICS.—A paper in no. 36 of the *Berliner Klinische Wochenschrift*, by M. Bernhardt, on a special kind of consentaneous muscular movements in hemiplegics, should be studied side by side with one by Dr. Westphal in the last number of the *Archiv für Psychiatrie*. The observation is original, and, so far as we know, forms a new contribution to the incomplete science of nerve-action.

Westphal begins by mentioning a few of the various movements that may occur in the limbs of hemiplegics withdrawn from the influence of the will, such as lifting of the shoulder in yawning, sighing, or in voiding excrements. Besides these, it

may happen that a hemiplegic, in wishing to contract certain muscles, puts in action their antagonists instead, a phenomenon described some time since by Hitzig. The especial peculiarity of the movement under notice is, that *when the patient stretches for instance one or more fingers, or the hand of the sound extremity, the movements are executed in an identical manner on the side affected by hemiplegia.*

A brief *résumé* of one of the cases given, will illustrate the subject. A man aged twenty-five, paralysed from his youth on the left side, was admitted to the Charité. Up to his twelfth year the hemiplegic side was subject to cramps, not, however, attended with loss of consciousness. Movements of the hand and fingers on the left side were impossible, unless the corresponding movements were made with the right extremity. As soon as the patient made any movement with the sound (right) side and fingers, this was repeated on the left, and it was quite out of his power to prevent it. A most singular impression was produced by this muscular echo—if the phrase may be allowed; thus, when on one occasion he scratched an itching spot on the face with his right hand, the left was raised for the same purpose. When *passive* movements of the right hand were made, the ‘echo’ was not observed. The muscular sensibility was entirely absent, so that he could not hold anything in his hand without keeping his eyes fixed upon it; the moment he took them off the object dropped. This peculiarity is not invariably associated with the phenomenon in question. The toes and foot of the left side partook of the same morbid ‘echo.’ What is the interpretation of these identical bilateral movements? Let it not be forgotten that Müller, of Coblenz, in 1844, noticed the tendency of muscles to act in groups of association. He remarks that practice is requisite for keeping one eye open, that many are unable to move the muscles of one side of the face only, and that the muscles of the extremities are to a less degree so implicated. In early life and in old age the same thing is seen. Westphal thinks that the pathological process which attacked the hemisphere of the side opposite to the paralysed one spared the large motor ganglia. Thus in left hemiplegia a part of the right brain would be so affected as to be unable to convey will-impulses to the left extremities; from the left brain impulses would continue to be directed on the motor ganglia, and thence through the decussation of the pyramids to the nerves of the right side. But the excitation set up by the influence of the will in the left brain is carried by the commissural fibres to the other side, where, meeting with the still intact large ganglia, it begets a movement in the left extremities, similar to that on the opposite side. The reason why, under ordinary physiological conditions, the same thing does not happen is, that by practice they are suppressed, owing to a restraining influence from the other hemisphere. When elderly persons suffer hemiplegia, these consentaneous movements are not seen, because, according to the above theory, the motor ganglion are affected, whereas, in the affections of childhood, parts only of the hemispheres are affected, as pathology has proved over and over again.

M. Bernhardt's remarks are on the case of a boy who, when eight years old, suffered from convulsions after scarlatina, and had right hemiplegia and aphasia, his stock of words consisting only ‘yes’ and ‘ah.’ The movements in the right shoulder and elbow were slower and made with less

force than those in the left; still, to some extent, they could be executed, and, when performed, excited nothing similar on the other side. If a movement were made energetically on the left side—if, for instance, the left forefinger were bent towards the wrist—it was repeated in the right hand, and could not be prevented in spite of all the patient's wishes. If the right hand were rolled up into a ‘fist’ the left remained quiet, but if the fingers of the right hand were moved alone, then the left fingers, especially the thumb and index, echoed the movement. Closure of the right hand caused only the slightest movement of the left index-finger.

Dorso-plantar flexion of the left foot produced an exactly corresponding action in the right foot, though nothing ensued on the reverse movement. The prick of a needle in the left hand only excited movements in the right hand. No opportunity for *post mortem* verification of Westphal's theory has as yet been offered, but M. Bernhardt agrees with him in the interpretation of the facts.

T. C. SHAW, M.D.

OBSTETRICS AND GYNÆCOLOGY.

REVILLOUT ON CONSTRICTION OF THE VAGINA, VAGINISMUS SUPERIOR, AND VAGINISMUS PROPERLY SO CALLED.—In the *Gazette des Hôpitaux* (August 29, 1874) Dr. Victor Revillout investigates a case that very much surprised him, and which appeared inexplicable from our present state of science.

Three years ago a young woman, a primipara, came into the Hôtel-Dieu to be confined. The labour was prolonged. The *interne* applied the forceps. The blades were apparently introduced with ease, the head of the fetus being at the brim. As the first efforts at traction were ineffectual, the forceps was removed, and the physician in charge was sent for. He arrived in three-quarters of an hour. On attempting to apply the forceps, he found it impossible to do so, as, a little below the os, the vagina was divided into two parts by what seemed to be a kind of double band, stretching completely across from before backwards, almost perpendicularly to the axis of the body. In spite of the affirmation of the *interne*, he refused to admit that the blades had ever been passed, and the bands were, in his estimation, cicatricial. He made a long incision on each side of the vagina parallel with its axis, almost perpendicular to the base of these two folds. The fetus was then extracted without difficulty.

The woman died three days afterwards of uterine phlebitis. In making a *post mortem* examination, not a trace of any cicatricial band could be found. The vagina was healthy and normal. Around the wounds there was no projection whatever to explain the necessity of making the deep incisions. Nevertheless, it could not be supposed that the practitioner was mistaken, in believing that he felt a very tense double fold projecting into the vagina. The assistant had also examined the vagina before the incision was made, and felt equally convinced, to his astonishment, that such was the case. It was now, however, evident that the phenomenon was a temporary one, and that for its explanation it was necessary to have recourse to the hypothesis of muscular contraction. But where was the portion of muscle that was contracted? It was scarcely possible to conceive that it was a part of the muscular fibres of the vagina, as

in that case the constriction would have been circular, and not from before backwards. Outside the vagina, there is no muscle as yet described that could produce constriction.

Shortly afterwards, another case came under observation, somewhat similar in its character, and which helped to explain somewhat the remarkable features of the previous one. A woman, a multipara, with old ruptured perinæum, complained that at times the act of intercourse was not only painful but impossible, from some constriction a short distance up the passage, although the vagina was, in general, sufficiently capacious. An examination showed at first nothing abnormal; she was desired to squeeze the exploring finger, if possible, and was able to do so with considerable force, relaxing or contracting the vaginal wall at will. On pushing the inquiry still further, it was found that there was a sensitive part a short distance inside the orifice of the vagina, and at the cervix. The slightest touch of these parts produced an effect similar to that called into action by the will.

Gosselin, under the name of Vaginismus superior, in his *Leçons cliniques*, published last year, speaks of a hyperæsthesia of the vaginal *culs-de-sac* without contraction of any kind. In acute vaginitis, from the painful spasmodic contractions of the vagina, a small body is, in some cases, incapable of being passed. As this condition has been denied by some authorities, amongst whom is Guéneau de Mussy, the writer made some careful dissections to see what were the anatomical relations of the muscles surrounding the vagina.

The vagina crosses the superior perineal aponeurosis very obliquely, from below upwards and from before backwards. On measurement of the length of the vaginal walls below this plane, the posterior is about double the length of the interior. The disposition of the muscular fasciculi is very peculiar in the perineal region. The vagina is divided by the superior perineal fascia into two parts, an inferior and a superior. The inferior or perineal portion is rich in muscular fasciculi; the upper part contains but few striated or voluntary fibres. On the lower half of the vagina the muscular fibres, for the extent of about seven centimètres, pass both from before and backwards obliquely towards the rectum, but more especially in the antero-posterior direction. At the point of junction of the posterior surface of the vagina with the anterior wall of the rectum, there is a small triangular space, with its base posteriorly. It is free of any muscular fasciculi, both behind and at the lateral surface of the vagina. The first fasciculi, which are inserted in the anterior surface of the obturator fascia, and in the centre of the aponeurosis, are more considerable than are generally described in anatomical works. They form as it were a trapezoid, nearly triangular, the fibres being spread out fan-shaped over the sides of the rectum, and encompassing the vagina to about the height of four or four and a half centimètres on its posterior margin. The inferior fasciculi do not deserve the name of elevators of the anus, for they really serve to constrict the vaginal orifice, as they are directed obliquely from above downwards, or from before backwards; but it is not so with the superior, which are oblique and represent a constrictor muscle, as described by Cruveilhier. There is another bundle of muscular fibres arising slightly more externally and more posteriorly, of triangular formation. They arise from the inferior surface of the superior aponeurosis, a little below the line of junction of the fascia with the vagina. They

strengthen the vaginal and rectal walls as they pass downwards, spreading out in the form of an elongated fan, whose base is about two centimètres. These fasciculi are exceedingly strong, and are composed of well marked striated fibres, which was verified by M. Damaschino under the microscope. A portion of these fibres lose themselves on the surface of the rectum; others seem to be inserted more distantly.

This curious disposition of the fibres has been never previously described. A contraction of these powerful fasciculi would narrow laterally the middle portion of the vagina, which was the case in the two above-mentioned patients. Their presence explains vaginismus, and their tonic contraction, the narrowing of the vagina in virgins, and in some women up to parturition; they also form the corrugated surface of the vagina.

BERNUTZ ON ESTHIOMÈNE, OR LUPUS OF THE GENITALS.—Dr. Bernutz, in the *Archives de Toxicologie* for July, 1874, states that he has only seen five cases of this disease during twenty-five years' hospital practice. It differs in no respect from the lupus that affects the body generally, but in the anatomical difference of the structure affected. There are two forms,—the erythematous and the tubercular. The former is the more rare, and is characterised by a reddish-violet blush, similar to what is observed in the face. It is always connected with the other variety. It consists of a softening of the cutaneous tubercles, which helps to diagnose it. The latter form is the more common, and is to be observed uniquely on the '*Privates*.' It is seen most characteristically on the mons Veneris, on the external surface of the labia majora, and on the perinæum. Its differential diagnosis, especially the ulcerative form, from two varieties of syphilitic ulcerations, is very difficult. It is the more so, as many affected with this disease have very suspicious antecedents. The chief signs are its dull red tinge, covered with a layer of imperfect epithelium, and finally, its progress; healing on one side, breaking out on the other, in parts oscillating between an ulcerated surface and cicatrices. Neither in syphilides nor in cancrroids is this peculiar feature observable, which in a marked manner distinguishes it from all other affections. He relates a case, occurring lately in a married woman, of a scrofulous history, but with no trace of syphilis. It seemed to result from poor living and bad air. She had given birth to a child a few months before; since that time she had had leucorrhœal discharge. Careful microscopical examinations of portions of the parts affected were made by M. Martin. The papillary vegetations were covered with thick layers of epithelium, more deeply of connective tissue, with an alteration in the lymphatics. There were a few fibrillæ of areolar tissue containing small round embryonic cells. The inner lining of the blood-vessels was formed of swollen epithelial cells containing ovoid and large nuclei. The cellular tissue which formed their base consisted of thin fibrillæ, and of elastic tissue in the form of a network. The most marked peculiarity existed in the lymphatics, which were thick, sometimes spherical, sometimes ovoid or cleft on section. The internal surface had one or two layers of epithelium. The cells of the most external of these two layers contained large ovoid nuclei stained red with carmine. In the innermost layer the cells were irregular, incom-

plete, having nuclei, large, spherical, at times stained by carmine through their whole substance, at others only at their margins. The central canal contained a coagulated material, uniformly coloured of a deep red with carmine. The changes were exactly analogous to those described by M. T. Renaut in the *Archives de Physiologie*, July 1872. The treatment consists in improving the general health, excising certain portions, and applying pledgets of lint dipped in tincture of iodine, and an opiate cerate, so as to exert pressure on the parts.

VALENTA ON BLEEDING TO DEATH OF THE FŒTUS DURING PARTURITION.—Dr. Valenta, of Laibach, relates, in Betz's *Memorabilien*, vol. xix. part 5, a case in which bleeding to death of the fœtus took place during parturition, through a rent in the umbilical vessels, which crossed transversely over the os.

A woman was delivered of her second child at full time. The mother stated that before the labour-pains began the waters ruptured, and from that time, up to the completion of the labour, which was of ten hours' duration, she had a continuous discharge of blood. At no time, however, was the stream observed by the attendants to be of a pumping character. On examining the after-birth, it was found to be about six inches in diameter, situated high up *in utero*. The umbilical vessels were given off from its lower margin; and, before uniting to form the cord they ramified in the surface of the chorion for about four and a half inches. The chord measured sixteen and a half inches. There were four veins passing from the placenta, which soon united to form two venous trunks, one of which, the smaller, arched outwards before uniting with its fellow to form one umbilical vein.

At the point of junction, and at a slight distance from it, were two rents. The two arteries united to form one trunk on piercing the chorion, which immediately gave off a small branch that coursed along with the above mentioned smaller vein. This was also torn across.

This case clearly shows the necessity of carefully examining the placenta of any woman where death of the fœtus has occurred.

VALENTA ON A CASE OF TWINS AT THE EIGHTH MONTH, WITH A PECULIAR RING-SHAPED LOW SITUATION OF THE PLACENTA, WITHOUT HÆMORRHAGE.—Professor Alois Valenta, of Laibach, reports in Betz's *Memorabilien* (vol. xix. part v. 1874) the case of a primipara, aged twenty-eight, who came under his care on November 13, 1871. The case was made out to be one of twins. Pregnancy had been prematurely interfered with at the eighth month, by a severe spasmodic cough, aided by the irritability arising from the great distension; and the patient had pains in the loins indicative of parturition. A head and a breech presented. Distinct labour-pains set in on November 19; but, as little progress had been made at noon the next day, the membranes were ruptured by means of an elastic catheter, and delivery completed. The breech case was delivered first; one child weighed three pounds, and measured fifteen and three-quarter inches long; the other weighed two and three-quarter pounds, and was fifteen and a half inches long. They were considered to be eight months' children, although the mother menstruated last on June 24. The infants died on the third day. There was some *post partum* hæmorrhage, which was arrested by the

injection of ergot *per rectum*, and the woman was discharged on December 9th. The placenta was especially noteworthy. There were two afterbirths, two amnia, and two choria. They were so connected one with another that, to judge from the rent in the membranes, their lower borders closely surrounded the internal os, forming a ring about five or six inches broad. The lower part of the ring corresponded to a rupture of the membranes, which was performed artificially in one only of the sacs, and was about six and a half inches in the transverse diameter. The four membranes formed a septum, dividing it into two nearly equal parts. The diameter measured five and a half inches. The average diameter of the ring, at its upper part, was eight and a half inches. The two ova were enclosed, as it were, by a belt formed of the two placenta, which accounted for the rather unusual occurrence of being able at first to distinguish the presentation of each fœtus with equal facility. There was no hæmorrhage, although the placental sites were so low.

VALENTA ON BIFID VAGINA AS A CAUSE OF IMPEDIMENT TO DELIVERY.—Dr. Valenta, of Laibach, relates in Betz's *Memorabilien*, vol. xix. part 5, the case of a primipara, aged twenty-six, who entered the clinique in labour; on examination, the os was found dilated about the size of a crown, the vagina still firm, and the membranes ruptured. On repeating the examination later on, the vagina felt narrower, and the os so small as to be incapable of admitting the tip of the finger. A closer investigation to account for this strange phenomenon disclosed a 'vagina duplex.'

The septum was very vascular, about four lines thick, and of a structure precisely similar to the vaginal walls; it passed from the surface of the urethra directly backwards, dividing the vagina into two nearly equal parts, the right being the smaller. The finger could be hooked over its upper margin, which was in close proximity with the os, and a finger introduced into the opposite vagina could be made to meet the other above the septum. By means of spatulas, the foetal head could be seen pressing down on the septum with each pain. It was divided with the blunt pointed scissors, care being taken to make the incision nearer to the posterior vaginal wall than to the anterior. There was considerable hæmorrhage from the anterior flap, which was ligatured. The head came rapidly down, completely arresting further hæmorrhage. Not a drop of blood came away after delivery. The ligature was removed on the third day for fear of causing a slough. The woman did perfectly well. Strange to say, on examining the vagina some short time afterwards, the anterior flap was entirely gone, and not a trace was left to show that such a condition had ever existed, whereas the posterior flap formed a firm prominent ridge. The uterus was normal.

W. C. GRIGG, M.D.

REVIEWS.

Bad Wildungen und seine Mineralquellen, mit besonderer Berücksichtigung ihren Heilkräfte bei den Krankheiten der Harnorgane. Von Dr. A. STOECKER. Pp. 34. Hamburg, 1873.

This is a very good account of Wildungen, given by Dr. Stoecker, one of the five or six doctors who practise there during the season. Dr. Stoecke r

having had occasion already to write of earthy waters generally, is able to treat of those of Wildungen in a discriminating way. Wildungen is in the centre of Germany, a two hours' drive from the nearest point on the Cassel railway. It is little known to the English, but presents many recommendations for those who are satisfied with a quiet and fairly comfortable style of life, in a rather picturesque country, with wooded hills and airy uplands. One may live either in the public establishment or in fair hotels.

The great characteristic of its wells, which are cold, is the presence of iron and carbonates of lime, soda, and magnesia, with abundance of carbonic acid. The latter gas is so abundant, that there is no difficulty in supplying what are commonly called steel-baths, which are quite sufficient, although for the present they are only heated by the addition of warm water.

One may have a pure, pleasant, and powerful chalybeate; one may have a weaker chalybeate, containing in the 10,000 parts about ten of carbonate of soda and of magnesia each; or one may have the water which is most used, a chalybeate containing a good deal of carbonate of lime, and a very little magnesia and soda.

As iron-wells, these waters are well suited for anæmic conditions and for great debility, and they have obvious applications in chlorosis, mucous catarrhs, and dyspepsia.

But the fame of Wildungen rests on its efficacy in affections of the urinary organs, vesical catarrh, tendency to stone, and albuminuria. The more alkaline waters find their application when lithic acid is present; the more earthy, when phosphates predominate. The waters differ from those of Vichy and Carlsbad in being cold. They are not so powerful or lowering as those of Vichy; indeed, they are tonic; nor are they depressing and purgative as those of Carlsbad. It seems to be certain that the waters are diuretic, that they sometimes remove albumen from the urine, that they are very useful in chronic cystitis, and some think that they are in some degree lithontriptic. They are largely exported, to the extent of 220,000 bottles and more, for use in urinary affections. The rationale of the action of earthy waters, such as those of Wildungen and of Contrexéville, in cases of this kind, is not very clear. With respect to the presence of so much iron in the waters of Wildungen, it is curious to recollect that old medicine attributed high virtues to iron-waters in calculous affections, when patients used to be sent to Tunbridge Wells and similar places for them.

J. MACPHERSON, M.D.

The Early Cases of a Typhus Outbreak. By T. J. MACLAGAN, M.D. Dundee. 1874.

This is a reprint of an article contributed to the *Edinburgh Medical Journal* by Dr. MacLagan, detailing the history of the origin of an epidemic of typhus fever, which broke out in Dundee in December, 1872. During the previous six months no cases of typhus had been reported in the town; but towards the end of December several cases were reported almost simultaneously from three widely separated districts, and Dr. MacLagan aims at showing how these cases may have originated, not *de novo*, but from infection derived from persons supposed to be suffering from diseases other than typhus, but which in his opinion were actually cases of that fever.

In the locality first affected, he traces the origin of the fever to a woman said to have died of *delirium tremens*, but in reality of typhus; and in the second locality, to three boys, who went through attacks of 'gastric fever,' cases which in all probability were typhus, seeing that the other members of this family afterwards contracted it. In the third locality a solitary case occurred; but no infection could be traced to it.

Dr. MacLagan details minutely the history of the primary cases of the epidemic, with the view of showing how infection may have proceeded from these two localities, and also from a family lately come from Aberdeen (in which town typhus was epidemic), to other parts of the town; and he is of opinion that the history of the origin of this epidemic goes far to show that the *de novo* explanation of the origin of typhus in certain cases is not tenable.

It appears to us that Dr. MacLagan, in attempting to refer the origin of all the primary cases to infection, has gone farther than the facts which he mentions warrant; and although we admit that there were many cases clearly traceable to infection, yet there were others the origin of which, in the absence of more positive proof than that given by Dr. MacLagan, would be explained more in accordance with the facts cited, by putting them down as cases of typhus which had arisen spontaneously.

The exclusively contagious theory of the origin of typhus is opposed by many well-authenticated facts; e.g., the origin of typhus in the Crimea and in Algeria, the histories of which have been given by Dr. Guillemin (see LONDON MEDICAL RECORD, September 23).

The paper, however, being the production of one who has had much experience of the disease of which he treats, is by no means an unimportant contribution to our knowledge of fever. It contains much valuable information on the subject of typhus; and we think it deserves to be read by those who are interested in the origin and spread of epidemic diseases.

ALEX. COLLIE, M.D.

Tropical Debility: A Treatise on the Causes and Treatment of Debility produced by prolonged Residence in the Tropics. By JAMES C. DICKINSON, late of the Bengal Medical Staff.

This little brochure belongs to a kind of medical literature which is unwholesome, and ought to be discouraged. The abiding impression left on our minds after reading it, is an unpleasant suspicion that we have been reading an advertisement.

It consists of thirty-eight small pages, without, so far as we have been able to see, a single original observation. They bristle with foot-notes, referring the reader to the author's 'works' on tropical diseases. Within the narrow compass already indicated, references of this kind occur nine times. The drift of the whole is, 'Come unto me, unto me, James C. Dickinson, ye tropical invalids, if you desire to be healed of your "debility."'

When the attention of the profession is pompously invited to a 'treatise' on any medical subject, they have a right to look for something better than a mere *rechauffé* of what has already been better said by Sir Ranald Martin, and a dozen other writers on tropical medicine.

We are sorry to have to write in such terms of any author; but unless criticism be allowed to become a farce, it is impossible to write of a publication such as this in any other terms. When a practitioner

has anything to say worth saying, let him say it; when he has nothing to say but to repeat what has been already said by others, he had better hold his peace. Publications of this kind may, to a certain extent, serve a particular purpose, but that cannot be the advancement of medical science.

MISCELLANY.

A CONFERENCE ON THE MANAGEMENT OF IDIOTS is to be held in Berlin on November 4, 5, and 6. To it are invited all superintendents of idiot asylums, and other persons interested in the subject.

MM. RICORD and Demarquay, during their stay in St. Petersburg, have been paying a visit to the hut-hospital, placed under the supervision of the ladies of that city. The *Journal de Saint Petersburg* states that these two eminent surgeons greatly admired the organisation and arrangement of the establishment, and were specially interested in the nursing institute attached to the hospital; so much so, that they intend to lay communications on the subject before the Academy of Sciences in Paris.

THE PHYLLOXERA.—In the MEDICAL RECORD for September 23, we gave an account of M. Lichtenstein's discoveries concerning the phylloxera. M. Balbiani, who has been appointed by the Montpellier Academy of Sciences to study the insect, entirely denies M. Lichtenstein's conclusions, and affirms that the phylloxera, found on the kermes oak, is an entirely different species from the one which now infests the vines. The kermes phylloxera has, he says, been described and figured by Geer, Kaltenschbach, and Leuckart.

A STRIKING DIFFERENCE.—Dr. A. Corlieu states in *La France Médicale* for September 30, that he had occasion to search the registers of the parish of Saint Antoine, preserved in the National Library. It was in the Cemetery of the Innocents, in that parish, that the dead bodies from the Hôtel-Dieu were interred; and Dr. Corlieu has ascertained that during the first six months of 1694 the deaths of the hospital amounted to 11,696. In 1873, during the same space of time, the mortality amounted to 770 for 925 beds.

COMPARATIVE ANATOMY OF THE PELVIS.—M. Topinard read a paper at the recent scientific congress at Stockholm on the general proportions of the pelvis in man and the other mammiferous animals. The object of this communication was to establish, by the help of the most careful measurement, the proposition already enunciated by M. Broca, that the contrasting types of the pelvis in man and quadrupeds show transitions in apes; the pelvis of the anthropoids more nearly resembling that of man, whilst that of the American apes bears a closer relation to that of quadrupeds.

AN ORIGINAL INVOCATION.—When in 1837 the late Louis Agassiz pronounced his famous *Discours sur l'ancienne Extension des Glaciers*, at the Congress of the Swiss Society for Natural Sciences at Neuchâtel, he enunciated the theory that Switzerland was formerly entirely covered by a thick layer of ice; a conclusion at which he, in common with other observers, had arrived in consequence of the striated and polished appearance of some of the rocks, and the evident removal of others. This was considered a frightful heresy; the whole assemblage was stupefied, until Leopold von Bach, one of the greatest geologists of the time, rose in much excitement, to denounce the new theory with unsparring severity. He was subsequently shown the striated surfaces near Neuchâtel, but still, not 'convinced against his will,' maintained that these appearances had been produced by students sliding over the rocks, and finished by retiring abruptly from the scene, ejaculating, 'O sancte De Saussure, ora pro nobis.'

TEMPERATURE AT GREAT HEIGHTS.—Professor Wahl, who accompanied Professor Wise in a recent balloon ascent, gives the following account of the temperature experienced. 'The maximum temperature observed was 97° at starting, and this continued at 1,300 feet. At 2,000 feet it was 96°; at 3,800 feet, 85°. The fall went on until, at the greatest altitude attained,—viz., 8,743 feet, the temperature was but 68°. It fell gradually as we descended, but was lower than in the ascent, owing, doubtless, to approaching twilight and the attendant lessening of the sun's power.' Observations were also made with a view to estimate the quantity and quality of any mechanical or other impurities of the atmosphere, but it will require some little time and careful work before any information on this point can be made public.

A NEW USE FOR EGGS.—An American contemporary (the *Boston Journal of Chemistry*) has discovered a surgical application of eggs. It asserts that the white of an egg has proved the most efficacious remedy for burns. Seven or eight successive applications of this substance soothe the pain and effectually exclude the burn from the air. Extraordinary stories are also told of the healing properties of a new oil which is easily made from the yolks of hens' eggs. The eggs are first boiled hard, the yolks are then removed, crushed, and placed over a fire, where they are carefully stirred until the whole substance is just on the point of catching fire, when the oil separates, and may be poured off. It is in general use among the colonists of Southern Russia as a means of curing cuts, bruises, and scratches.

PROFESSIONAL SECRECY.—Two of the most distinguished surgeons of Milan, MM. A. Turati and C. Tamburini, have just been condemned to a fine of fifty francs each for not having given information of a duel which had serious results. The question of professional secrecy was brought forward in the matter; but the law was nevertheless rigorously carried out. In consequence of this decision, Professor Zucchi has demanded that the General Congress at Venice should pass a measure to relieve members of the medical profession from those unpleasant complications which occasionally trammel them in the performance of their professional duties. The Italian medical journals, the *Annali Universali di Medicina*, the *Archivio di Chirurgia* of Naples, and *La Salute* of Genoa, enter into all the details of the affair with great interest.

A JAPANESE MEDICAL JOURNAL.—A bi-monthly medical journal in the Japanese language, entitled *Kiu-Si-I-Setzu*, or *Modern Medical News*, is now published at Yedo. It is published by the Imperial Government, has a guaranteed circulation of one thousand copies, and is edited by Dr. Stuart Eldridge, an American physician connected with the medical staff of five large native hospitals, and who has a number of native students attending his clinical lectures. The first number contains:—1. Lectures on Urethral Stricture, by the Editor (Lecture I.); 2. Surgery without Hæmorrhage (Esmarch's method); 3. Apparatus for Digital Dislocations; 4. Government Inspection of Coal-oil; 5. The Relief of Pain; 6. Necessity for the Education of Midwives in Japan; 7. The Salts of Copper in Cholera; 8. The Nitrite of Amyl, a new remedy for Asthma; 9. Rules for the Administration of Arsenic; 10. Oxide of Zinc in Diarrhoea of Infants; 11. Tinctura Ferri Chloridi in Small-pox; 12. Gelatine Suppositories in Fæcal Accumulation; 13. Treatment of Syphilitic Onychia; 14. Tinctura Ferri Chloridi in *post partum* Hæmorrhage; 15. Ergotine in Hæmorrhage. The variety and freshness of the table of contents show that our Japanese friends now have the opportunity of becoming acquainted with the newest methods and results of European surgical and clinical investigation. Their remarkable power of mental assimilation and imitation will doubtless lead them to avail themselves of this advantage to the benefit both of themselves and of their patients.

CHOLERA STATISTICS.—The *Gazette d'Augsbourg* states that a mass of statistics were collected during the last cholera epidemic at Munich (1873-1874) with a view to the future guidance of those specialists whose task it will be to discover how this scourge is propagated, as well as how to combat and eradicate it. The tables prepared at Munich indicate the streets and localities where the disease broke out, and those which escaped it; the number of cholera cases and deaths which occurred each day, with the period of their duration; also whether the cases occurred during the winter or the summer season. Two distinct outbreaks were noted during this epidemic at Munich, the one lasting from June 26 to November 16, 1873; the other from November 27, 1873 to April 27, 1874, the day when the disease finally disappeared. Munich contains about 400 streets, of which 122 escaped the disorder. Of these latter ninety-three were not drained. The total number of cholera cases amounted to 3,040, of which 1,466 were fatal. The largest number of cases (thirty-nine) were registered on August 11; the largest number of deaths (eighteen) occurred on the fifteenth of the same month. December 8 saw the greatest number of winter attacks; they amounted to fifty-nine, and the same day and January 24 showed the largest death-rate of the period.

THE HAIR AS AN INDICATION OF RACE.—At the recent meeting of the French Association for the Advancement of Science at Lille, a member of the Anthropological section made a communication on the subject of the importance of the difference of the hair as characteristic of different nations. He drew attention to the insufficiency of craniometric characteristics, the great complexity of which does not give any results superior to the characteristics drawn from the skin, the proportions of the limbs, the language, etc., and he submitted to his colleagues a series of postulates, which were strongly contested. M. de Quatrefages especially, justly protested against any classification founded on a single characteristic. It is however, none the less certain that there is a more marked difference between the hair of Chinese, Negroes, Scandinavians, Hottentots, and Americans, than there is in the form of their skulls, and that one glance will suffice to distinguish the hair of a native of Guinea from that of a Papuan or a Malay, whilst the cranial diagnosis will only be at all certain if it rests on an average deduced from numerous examples. Besides this, every anatomical characteristic may serve for a starting-point for the human series, whilst it is incontestable that the hair, whatever may be the value of the order in which it is found, represents one of the most lasting and most persistent features of the human race.

ETHNOLOGICAL RELATIONS OF THE OCCIPITAL BONE. M. Hovelacque has studied the occipital bone, or rather the transverse lines and arcs of that bone, in all the races of man. Taking as the chord of the arch, the diameter comprised between the two postero-lateral fontanelles, he brings two transverse arcs into relation with that chord; the first is described by the curve which, on the exterior, is followed by a line corresponding to the line marked on the anterior surface by the lateral sinuses of the occipital, which both spring from the postero-lateral fontanelles. This arc corresponds to the division of the cerebrum and cerebellum. The second arc, springing from the same extremities, takes its course in a horizontal line, parallel to the visual and condylo-alveolar planes. M. Hovelacque has compared the relation of each of these arcs to the diameter with extraordinary patience, and has obtained results in conformity with craniology in general, whence it would seem to result that a single measurement can determine ethnic classifications analogous to those given by the mass of measurements. Thus he has shown the relation between the Bretons and the Auvergnats, as M. Broca had already done by the nasal indication. Thus, the classification of the Malayan and the Ural-altaic group is confirmed by that cranial measurement, which may be termed the indication of the transverse curvature of the occipital.

HOMINAL versus ANIMAL VACCINATION.—Through the instigation of Dr. Guilbert, a practitioner in Paris, the Prefect of Police addressed a letter to the Academy of Medicine, requesting information as to the advisability of the revaccination of those persons who, in 1870, were vaccinated direct from the cow. This was the year in which there was such a panic in Paris, owing to a severe epidemic of small-pox, that people lost confidence in 'hominal' vaccination, and gave the preference to animal vaccination. At the end of the same year and the beginning of 1871, another epidemic of small-pox broke out, and proved fatal to about 14,000 inhabitants in Paris. This was attributed by M. Guilbert to the inefficiency of animal vaccination as an antidote against small-pox; and it was on this representation of the case that the Academy was called upon to report on the subject. A committee was formed to investigate the matter, and M. Blot, the reporter, stated that inoculation from the cow, when properly performed, is at least equally as efficacious as arm-to-arm vaccination. As regards the superiority of one over the other as a preservative against small-pox, the committee could not then express an opinion; time alone could decide. The reporter, however, remarked that in either case the preservative property was only temporary. This view of the case was supported by M. Depaul. M. Guérin stated that the preservative property of hominal vaccination lasted at least fifteen years, and he asked how it was possible to know whether the immunity produced by animal vaccination lasted as long, as it was only in 1868 and 1869 that this latter mode was introduced. MM. Blot and Depaul retorted that the immunity produced by human vaccination might last ten, five, or only two years. As to the great mortality from small-pox in the epidemic of 1870 and 1871, M. Depaul had shown that, out of the 14,000 deaths, children formed a minor proportion; it was individuals of eighteen to twenty-five or thirty, all of whom had been vaccinated with hominal lymph, that formed the largest proportion. M. Depaul concluded by stating that the accusations brought by M. Guilbert against animal vaccination were unfounded, and reiterated his opinion that animal vaccination rendered as much service as hominal. Nothing, he added, proves that children vaccinated from the cow are more liable to contract small-pox than those inoculated from arm to arm. Here the discussion ended, with MM. Depaul and Guérin and their respective partisans as far as ever from each other.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17s. 4d.; free by post, 19s. 6d.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & Co., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The First Volume, containing upwards of Two Thousand Articles abstracted and compiled by a staff of Fifty Hospital Surgeons and Physicians, is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for the year 1873 are also ready, price 1s. 6d. each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & Co.—Calcutta: THACKER, SPINK & Co.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & Co.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & Co., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, OCTOBER 21, 1874.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

JOUSSET DE BELLESME ON THE VENOM OF THE SCORPION.

In a recent number of the *Annales des Sciences Naturelles* (tome xix.) Dr. Jousset de Bellesme records at some length researches on the venom of the scorpion. Swammerdam, in the seventeenth century, declared that the sting of the scorpion was only a sheath in which the true poison-dart was concealed; in other words, that it was analogous in structure to the sting of the bee. Redi contradicted this, but could not prove the presence of any orifices for the ejection of the poison. Vallisneri, Leeuwenhoek, Ghedini, and Maupertuis discovered the orifices, and the latter figured them as two in number. In 1699, Melchior Frick asserted that vipers and scorpions were only dangerous from the puncture which they made, no poison being transmitted into the circulation; but this was contradicted, with proof, by Redi. In 1731, Maupertuis again made trial of the question, but, as his researches were contradictory, he 'came to a conclusion, worthy of Aristotle, that scorpions are not at all times venomous.' Neither Amoreux in 1789, Guyon in 1852, nor Blanchard yet more recently, have advanced the subject many more steps by their researches.

Only two kinds of scorpions are found in France. *Scorpio Europæus*, which is only about from 3 to 4 centimètres in length, lives in crevices in buildings; while *Scorpio occitanus*, which is about from 7 to 8 centimètres long, is less common, and is found only in the open country in waste sandy tracts, concealed simply under stones, for it makes no subterranean excavations. As the sting of *Scorpio Europæus* is very frequent, an antidote will accordingly be found in all the druggists' shops, and even in private houses, in Provence, in the shape of *huile de scorpion*, which consists simply of a number of these offending arachnids macerated in olive oil. As the sting is never dangerous, this remedy is found, of course, in all cases singularly effective. With the sting of the larger kind it is very different. The puncture is fearfully painful, so that, according to Ehrenberg, who has experienced it, most serious nervous complications may follow in feeble persons. The point of puncture turns black, the skin becomes tense like a large phlegmon, and then follow rigors, fever, vomitings, hiccough, convulsions, syncope, and muscular tremors.

The poison-apparatus of the scorpion is lodged within the sixth and last caudal segment [probably the homologue of the mesial element, or 'telson,' of the last segment of the tail of a macrourous crustacean, e.g. a lobster, or crawfish.—*Rep.*], which is of a rounded flask-like shape, and terminates in a horny blackish dart, recurved and very sharp.

Within the ampulla are contained two little glandular sacs, communicating by a common duct, which extends into the dart to terminate near its point by two longitudinal slits, which are somewhat difficult to see. It is through these that the venom is injected, by the aid of the contraction of muscular fibres, which invest the glandular saccules. In its natural attitude the tail of the scorpion describes a curve; but when the animal imagines itself to be completely sheltered against all dangers, it rests on one side or on the other, upon the ground. It is by a sudden extension of the tail that the dart, after being first brandished over the head of the scorpion, is launched against the body of the victim; and, however small be the prey, it is never brought to the mouth until it has been pierced by the sting. This is a measure of precaution; and that it is not an inherited instinct, but is probably acquired by bitter experience, the following instance will show. M. de Bellesme gave one day to a captive scorpion, which he had hitherto been feeding upon flies, a spider of the size of a pea. The scorpion, having seized its prey with its chelæ, stung it *en règle*, but, probably owing to some flow of blood, the poison took no effect. The spider, *sicut est mos*, feigned death, and as the scorpion, deceived by this *ruse*, was about to transfer its prey to its mouth, the spider suddenly buried its 'mandibles' in the base of one of the chelæ of the scorpion. The latter stung its victim anew, and, this time with effect, but had scarce time to enjoy its victory before it began to show signs of discomfort, and was afterwards seized with tetanic spasms, from which it did not recover till the following day, when it ate a fly with good appetite. The scorpion always attempts to sting its prey in the thorax, death taking place much more rapidly when this site is luckily hit upon, the rapidity of its access being in the inverse ratio to the size of the victim.

In order to procure as much poison as possible for the sake of experiment, it was found necessary to fix scorpions on metal wicker-work, as milch-cows, so to speak, of poison (*vaches à venin*), and to feed them with flies: their tails being tied up—'a somewhat delicate operation'—in order that, when the poison was required, the terminal ampulla might readily be cut off with a pair of scissors—a rough but the readiest method of collecting. The secretion then having been squeezed into a watch-glass was ready for investigation. This fluid is colourless, transparent, only becoming slightly opaline when the gland has been much in action, but never viscous nor treacherous. It dries rapidly, forming a brilliant varnish on the surface of the glass. It is, like all other poisons, decidedly acid in reaction, and is very soluble in water in all proportions, but is sparingly soluble in alcohol, being probably insoluble in absolute spirit, and is insoluble in ether. Its density is a little greater than that of water. Owing to the difficulty of procuring enough for analysis, its chemical composition must for a long time remain doubtful, though it is probably a colloid substance. Under the microscope it appears as a highly refracting liquid, in which are here and there some epithelial cells and fine granules. The normal quantity of the secretion at a time in the poison-ampulla varies, of course, according to the size of the scorpion, but it is always inconsiderable; an animal seven centimètres in length having about eight milligrammes. The quantity which presents itself at the tip of the sting when the animal is excited is not more than a quarter of the whole contents. The

quantity of eight milligrammes is enough to kill an average-sized dog when inoculated with it, while the amount fatal to an insect is extremely little, as the following experiment will show: To a specimen of *S. occitanus* about three centimètres long, and whose poison-ampulla must have contained only five décimilligrammes of fluid, flies were given, and, as soon as stung, removed. Sixteen died successively in a few seconds, the next four succumbed in twenty seconds, the next two survived some time after the puncture, while, finally, the scorpion would not touch the twenty-third.

M. de Bellesme employed for some of his experiments the little green frog 'Rainette verte,' (*Lilla viridis*), not only because the common frog was scarce, but from the greater vascularity of the skin, absence of pigment, and fineness of the intradigital web in the former. It was established by preliminary experiments that the three following conditions must all be present in order that the puncture of the sting should take proper effect.—1. The orifices of the sting must not be obstructed. 2. Ejaculation of the poison contained in the ampulla must take place. 3. The poison must be fairly inoculated into the tissues of the animal experimented upon. The sting itself was used as the instrument of inoculation, the poison being squeezed out by means of a pair of forceps. Experiments were made upon dogs and pigeons, as well as upon frogs; those made upon the latter being, however, the most satisfactory. At the moment of puncture most severe pain is experienced; then, after the animal (*e.g.* a frog) has tumbled about for a few minutes, a violet-red discoloration is seen to extend from the wounded limb (*e.g.* a hind leg), over the abdomen and back. If then the skin be carefully examined, the capillary network will be seen to be finely injected, the superficial cutaneous vessels being apparently clogged up by coagulated blood; and in the interdigital web, as well as in the tongue, small red spots will be visible. The general sensibility of the body is much increased, the punctured limb is extended, and all attempts to flex it are attended with evidences of pain. The respiratory movements are gradually abolished, the pulsations of the heart become less frequent, and the animal finally dies. A pigeon died in two minutes after the subcutaneous injection of only six décimilligrammes of the poison, while no less than fifty-seven minutes were required for the same dose to take fatal effect in a rainette. Not only were the physiological effects readily visible to the naked eye noted, but the blood was carefully examined after the addition of the poison, both when circulating in the vessels and as a fresh drop placed on a glass slide. The three following points were established. 1. The poison of *Scorpio occitanus* acts directly upon the red corpuscles of the blood in vertebrated animals. 2. The immediate result of its action is to cause the corpuscles which have been in contact with it to lose the property which they possess, under ordinary conditions, of readily gliding one over the other. 3. In losing this property they become agglutinated together, and adherent to corpuscles as yet unaffected, in such wise as to form small masses, which plug the fine capillaries, and thus become a complete obstruction to the circulation. If the quantity of the poison be sufficient to cause a speedy death, this will be brought about through embolism and arrest of the circulation; but if the amount be insufficient, those phenomena will take place which always supervene when some obstacle is introduced

into the circulation, *e.g.* œdema and cellular infiltration, which latter can be better seen in mammals than in batrachians.

[The following words of Baglivi, who wrote at the end of the seventeenth century, in cap. viii. of his Essay upon the Tarantula, have a wonderful significance when read by the light of M. de Bellesme's conclusions. 'Any one may infer from the symptoms that have been so often repeated, that the poison of the Tarantula has a tendency in it to curdle or thicken the blood, and there needs no further evidence of that than the sudden oppression of the pulse, anguish at heart, great difficulty of breathing,' etc.—*Rep.*]

A propos of the dispute between Charas and Redi—'le gentilhomme florentin,' as the former termed him—as to whether the poison of the viper could be swallowed with impunity, M. de Bellesme observes that physiologists, when making experiments upon the action of a poison—be it of the viper or of the scorpion—on the digestive tract, never vary the conditions, and thus always arise at the same result. For, from the difficulty of procuring enough of the poison, a sufficiently large dose is not given; for, after all, it is very probable that the so-called innocuousness depends solely upon a question of quantity.' It is probable, too, that the poison, insignificant in quantity, becomes readily diluted by the gastric secretion, and also by such fluid as it encounters in the stomach, for the energy of action of the poison of the scorpion decreases rapidly when diluted with water, while a dose of strychnine, on the other hand, has the same effect, whether sparingly or copiously diluted with water. The fact, too, established by Claude Bernard, must not be left out of account, that the absorptive power of the digestive tract is much less active than that of cellular tissue. [The mere fact, too, of the poison of the scorpion being 'of a colloid nature,' tends to show that it would not readily dialyse.—*Rep.*]

Unfortunately, from the researches above recorded, no therapeutical conclusions can as yet be deduced. As far as the sting of *Scorpio Europæus* is concerned, the usual time-honoured palliatives may be used; but as regards *S. occitanus*, the rarity of its sting is the only source of comfort, for here such remedies as saliva, 'huile de scorpion,' sal ammoniac, and carbolic acid, are quite useless, seeing that they have no action on the blood-corpuscles affected by the poison, and already launched into the circulation. The restoration to the corpuscles of their lost physical properties is a problem which therapeutics have not yet solved, and the only hope lies in the administration of ammoniacal or alcoholic preparations, if a period of reaction should fortunately supervene.

J. C. GALTON.

ON THE TREATMENT BY MINERAL WATERS OF CHRONIC DISEASES, AND ON THE PRINCIPAL SOURCES ADAPTED TO THE VARIOUS MORBID CONDITIONS. BY M. GUBLER.*

The selection of the mineral waters most appropriate for each pathological case, is undoubtedly one of the most complicated and difficult problems which the physician has to solve. He has to direct and watch their rational application in the numerous

* *Journal de Thérapeutique*, no. 10 et seq.

circumstances under which they prove themselves useful, either by their temperature, by their medical constitution, or by their dynamic force. By their temperature they adjust themselves marvellously to all the processes of thermal hydrotherapy. As mineral waters, varying in the nature of their elements and their mode of combination, in their allotropic conditions and in their latent forces, they are powerful modifiers of the blood crasis, and of nutrition and change of tissue. They are not usually heroic medicines, but just the reverse; they act as it were by insinuation. For the bulk of heroic remedies they substitute dynamic force, for their violence they substitute time, and they display the triumph of minim, I shall not say infinitesimal doses, over the coarse compounds of the pharmacopœia. Perfect types of alternative medicines, they display the advantages, as well as the disadvantages, of that class of remedies. If their effects have often to be waited for, they are wonderfully permanent, whether they are metatrophic or metamorphic. Such qualities render mineral waters especially useful in cases of chronic disease. It is easy to affirm this generally; the difficulty is to pronounce what water is most suited for the particular case. To do this satisfactorily, we must first make out the exact pathology of the case, and then select one of the many claimants for popular favour in such cases.

It is said vaguely, the physician must be guided by the nature of the case. Does that mean its pathological nature, or does it include its etiology? In reality, neither the morbid entity nor its specific cause should influence our determination much. We deceive ourselves, when we think we are obeying the indication of syphilis as a cause, in prescribing mercury; in reality, we are meeting the wants of a special anatomical condition engendered by the virus. This is so true, that in the natural evolution of the case, iodide of potassium becomes more suitable for it than mercury; and that, on the other hand, when a state of the organism resembling that produced by syphilis occurs, mercury and the alkaline iodide render the same benefits as in affections of syphilitic origin. In like manner a physician, when prescribing a mineral water, should not preoccupy himself with syphilis, or gout, or scrofula, considered in the abstract; he has to determine whether the syphilitic, or gouty, or scrofulous patient presents such and such a localisation, such and such a form, such and such a stage of his affection, and such and such a state of constitution and of general health. In short, it is the patient, not the malady, that he should consider.

But some one will say, it is vain to attack a symptom locally, unless you at the same time attack its diathetic cause. Far from me to undervalue the importance of the cause, but it must be recollected that causes may be of various kinds, but that of the causes only one is of importance in the therapeutics of a case. A headache depending on a syphilitic intracranial node can only be cured by causing the absorption of the node; we have no occasion to think of the virus which was its primary cause, we have only to make out the condition of the system, and use the means acknowledged to be efficacious in removing such conditions. Or, take the case of gouty arthritis, we have only to calm the local inflammation, while we endeavour to modify the general morbid condition by trying to remove the excess of lithic acid from the blood. In fine, rational practice consists in attacking directly the apparent effects,

while we endeavour to modify the morbid condition which appears to be their cause.

Applying these principles to certain of the cases which seek relief from mineral waters,—take a cutaneous affection, for instance—it is not enough to think only of the cause, which may be scrofulous, arthritic, or herpetic, but we must especially attend to the local or general affection of the organism, to its acute or chronic condition, to its dry or moist state, to visceral complications, to plethoric or anæmic conditions, which yield the physiological indications.

The physiological indications of chronic maladies, which are ordinarily fulfilled by common pharmaceutical remedies, may be equally so by mineral waters, as my physiological classification of them shows.

In it, we see stimulant treatment represented by the very hot, the gaseous, and the sulphur waters. Sedative treatment comprises the indifferent waters, mucilaginous, acidulated, tepid, or cold. I do not speak of waters which might be used as anæsthetics, those which contain carbonic acid and perhaps those which contain carburetted hydrogen. There are waters which are astringent or styptic, and which may have a tonic and hæmostatic action: there are the acids, the sulphate of iron ones, those containing alum, or iron and copper. Certain undoubtedly diuretic waters are to be found among the indifferent ones, the mixed salines, and those containing nitre. Others are powerfully purgative, the ones with sulphate of soda and magnesia, with chloride of sodium, or with a mixture of the two. There are also dialytic waters; these are the alkaline ones and those containing lithia.

Many mineral waters are excellent remedies for improving the digestion, acting variously as laxatives, as tonics, as stimulants at once and anæsthetics (the gaseous waters), or directly on the stomach as acid, as absorbent, as alkaline and calcareous waters. There are other waters which exercise a marked influence over the blood crasis, and thus sometimes favour, sometimes modify nutrition. Such are the iron and manganese waters, the mixed salines, and specially those whose very mixed composition recalls that of the serum of the blood. They deserve the name of true mineral *lymph*. The iodine and iodo-bromine, the sulphur, the arsenical and the copper ones, are eminently alterative, whether by changing the composition of the blood, the conditions of nutrition, or the constitution of the tissues.

Lastly, we might establish a class of waters, toxic to the lower organisms, and which might be employed as parasitocides, vermifuges, antiputrescents. Such are the sulphur, the hyposulphite, the arsenical, and the bituminous ones.

Mineral waters, it is thus apparent, have varied enough powers to respond to many indications. These powers are further extended by the great variety of ways in which they may be employed. One water is purgative in large doses, and may be tonic when taken in smaller. Another which induces fever when used at its natural heat, is found to be sedative when it has cooled down. Besides this, in many cases the mineral water has, as adjuncts, moral causes, such as arise from elevation of site or from climate. Hence the logical necessity of distinguishing the three following conditions, the complexity of which goes on constantly increasing. 1. The physiological action of a natural mineral water in itself; 2. The effects of the traditional method of treatment; 3. The influence of treatment

at the source, combined with the advantage of hygienic and climatic conditions, usually favourable. In passing in review the morbid affections treated usually with mineral waters, I shall endeavour to follow a rational order, in hope of avoiding repetitions. I shall first speak of general conditions, as weakness, nervous depression, anæmia, obesity, or unnatural leanness; next of scrofula and lymphatism; then of affections of the respiratory organs, and of the genito-urinary organs of both sexes. The affections of the digestive canal, and of its appendages, will follow. And I shall finish with skin-diseases and syphilis, metallic poisoning, brain-affections, and surgical diseases.

1. Treatment of Anæmia.

What I am going to say of anæmia, applies equally to conditions of languor and loss of nervous energy.

In a therapeutic point of view, anæmia may be divided into transitory, persistent, and constitutional.

Transitory anæmia, the consequence of privation of fresh air and light, of inanition, of excessive losses, as hæmorrhages, or of acute illness, may, strictly speaking, do without mineral waters. Rest, nourishment, hygiene, suffice to restore the blood to its natural condition.

In persistent anæmia, kept up by dyspepsia, diarrhoea, or by disturbance of the respiratory or circulating system, or other chronic affections, hygienic treatment by itself is insufficient. The complications or causal affections must be treated; we must order a residence among the mountains or at the sea-side; sea-bathing, and waters that alter the digestion and the circulating fluid. Several kinds of waters serve to alter the constitution of the blood. Thus waters containing salts or chloride of sodium supply neutral salts to the serum; saline waters containing lime bring one of its elements to the osseous system; the most powerful ones of all are the iron waters, and those containing iron and manganese. But all iron waters have by no means the same value, and their value is not to be measured merely by the dose of iron which they contain. In point of efficacy, I divide them into three categories. Lowest are the waters which contain no gas, next come gaseous iron waters, and the first rank is occupied by the perfect waters, which are at once ferro-saline and gaseous.

The non-gaseous iron waters are often rich in iron, but they are apt to lie heavy on the stomach, in the absence of the natural condiment, carbonic acid; nevertheless, they have undoubted restorative powers. They are divided into carbonated crenated iron, and sulphated iron. The last, less numerous and less important, are generally mixed, and act on the blood by their oxide of iron, while the sulphate is more or less astringent.

The chief non-gaseous waters containing carbonate of iron as those of Candé, La Bauche, Aumale, Sainte-Quitterie de Tarascon, Lac Villers, Saint-Dizier, Chateaugontier, Forges, Gournay, Cambo, etc.

The gaseous mineral waters, which taste like champagne, are not only more agreeable, but are lighter, and are usually better borne by the stomach.

The most celebrated spas out of France belong to this class. But nevertheless France is as rich as any other country in Europe in waters of this kind. To Pymont, Griesbach, Schwalbach, and Spa, we can oppose Renlaigue, Vic sur Cére, Prugnes, Arlanc,

and others in the centre of France—and particularly Oreza in Corsica. But it is to be regretted that most of those places are not supplied with sufficient establishments. There is a good establishment at Oreza—and that at Vic sur Cére, situated on the railway in a picturesque part of Cantal, deserves to be more visited than it is.

Among the gaseous iron springs, which emerge on all sides from the flanks of the extinct volcanoes of Auvergne and Vivarais, the chief one is that of Cayla, as gaseous and containing more iron than any of the springs out of France. Next come Cassuéjols, Arlanc, Prugnes, and Andabre, quite equal in mineral contents to Schwalbach. Of these Prugnes and Andabre only have small establishments, but access to them is difficult.

But superior to all the ferro-gaseous waters are the true mineral *lymphs*, containing all the neutral salts of the serum, of which France contains many specimens. Vic en Carladès, Chateaneuf, Renlaigue, Saint-Maurice, Saint-Nectaire, are some of the chief ones. The water of Renlaigue, which is sold in Paris, has yielded me good results, and Saint-Nectaire has cured cases of chlorosis, which had resisted all other treatment.

Simple anæmia and chlorosis may yield to plain carbonate of iron waters, which are scattered everywhere in great abundance. Other things being equal, those waters are to be preferred which contain manganese also, as those of Candé, Casteljaloux, and Luxeuil.

These same affections, when complicated with dyspepsia, and rebellious to ordinary treatment, should be combated with the gaseous waters of Camarès, of Oriol, of Vic sur Cére, and especially of Oreza, and failing these, with the waters of Spa, where the arrangements of the establishment are admirable.

Iron, gaseous, and alkaline waters will be more efficacious than others, in certain states of dyspepsia; for instance, Andabre, Augnat, Montbrison, Neyrac, and the source Mesdames of Vichy.

If necessary, if disturbed digestion be the origin of the morbid state of the blood and of nutrition, one must order waters containing more alkali than iron, such as Boulou, Courpière and Marclos.

When chloroses and anæmias are desperately obstinate, we still have in reserve the mixed saline or chloride of sodium and iron waters, such as Rouzat, Saint-Maurice, Vic sur Cére, Chateau Guyot, Chateaneuf, and Saint-Nectaire.

Certain cases of torpid chlorosis are advantageously modified by the thermality of some of the saline or sulphurous waters. Among these may again be placed the red spring at Saint-Nectaire.

Menorrhagia or hæmorrhagic chlorosis frequently requires aluminous iron waters, that is, sulphate of iron, which is often associated with sulphate of alum. To this category belong Passy, Auteuil, Chemillé, the source Galtier at Cransac, and Dominique, and Saint-Louis at Vals.

Anæmic patients, affected with bronchial catarrh, may profit by iron sulphur waters, as those of the south gallery at Luchon, of Audinac, Aumale, Bagneres de Bigorre, Mondang, and especially the arsenio-sulphurous iron of Sylvanès (Aveyron). This last, so remarkable for its thermality and its complex constitution, is especially to be recommended to anæmic patients with skin affections, who may also profit by weak arsenical waters, such as Hammam-Meskoutine and Luxeuil.

Anæmic patients of gouty habits may profit by the alkaline iron waters, already recommended in dyspepsia.

Finally, impoverishment of blood, allied to lymphatism and scrofula, where there is family predisposition to tuberculosis, or if complicated with albuminuria, specially requires the saline iron waters of the centre of France.

[The translator ventures to say, that M. Gubler takes a too patriotic and too favourable view of the resources of France in iron waters. Some of the places he enumerates have been omitted. But of those he mentions, a great many are scarcely known by name even to Frenchmen. Their powers have not been fairly tested, and their resources are undeveloped. Orezza, the best of them, is unfortunately in Corsica. English could not visit most of these springs with any comfort. They might be moderately comfortable at Saint-Nectaire, Vic sur Cére, Forges; and at Vichy, Luchon, Bagnères de Bigorre would have every comfort. Manganese and arsenic have a good deal of value attributed to them in France, and Luxeuil or Vals have comfortable arrangements].

J. MACPHERSON, M.D.

(To be continued.)

MAJOR ON THE HISTOLOGY OF THE MORBID BRAIN.*

Mr. Major, in a continuation of his series of articles on the histology of the morbid brain, which is especially devoted to the consideration of the conditions presented by the cortical substance in cases known as senile atrophy, says that we know the great cause of disease and destruction in the nerve-cells to be a deficient or vitiated nutritive supply; that in senile atrophy we should expect to find the simplest forms of degenerative changes; that in judging of these changes an impediment is presented by the effects which must be exerted by age upon these parts; that, in a child of about eight months, the nerve-cells throughout the entire depths of the grey matter are found to be almost uniform of size, circular in form, and almost entirely destitute of branches; in the adult, these cells are arranged in numerous rows, and present various forms and intricate connections, while as years advance, and mental strength declines, corresponding alterations may be expected to be found. From a careful comparison of the cells, specially directed to ascertain the relative extent to which they suffer, he is led to think that, in the majority of cases of senile atrophy, it will be found that the large pyramidal cells which form a conspicuous band about midway in the depth of the cortical substance, are those in which degenerative changes are most constantly and distinctly marked. In the small round, or oval cells, structural changes are comparatively rare, though they must exist, as numbers of these cells completely disappear. The atrophic change is chiefly noticed in the frontal and parietal regions, where the large cells are most numerous. The cells at the extremity of the occipital lobe are less affected than in any other portion of the grey matter. The form of disorganisation invariably present is the granular condition of the large cells. The first stage of this

process is that these cells lose their sharply defined and more or less triangular appearance, and acquire a swollen and inflated aspect. The nucleus likewise becomes swollen, larger, and more or less oval. The nucleoli become very distinct, partly because the pigment of the cell is absent, and partly because the nucleoli readily absorb the staining solution. In the next stage a deposit of granules is observed, inside or outside, imparting a yellow or opaque appearance. Masses of these granules may either fill one half the cell, or cause a bulging and deformity at a particular point. Gradually the interior of the cell is completely filled with yellow bodies, as if artificially coloured; then the walls give way and shrink, leaving the nucleus and its nucleoli surrounded by granules. The holes observed in the grey matter are not seen in the healthy subject surrounding the cells as in atrophy. Thus the nucleus proves to be the most persistent part of the cell, surviving long after the latter has disappeared. The granules have been believed to be fatty in nature, but this view is not established. In the first or outer layer of the small nerve-cells, the change is rather that of shrivelling than of degeneration. He has not observed hypertrophy of the nerve-cells in atrophy, but has met with it in general paralysis of the insane, but does not doubt its existence in the former, though exceptional in both. Their branches, supposed to be increased in number, are, by him, regarded as enlargements of those normally present. The confusion in the rows of cells is believed to prove that certain of their number have disappeared. In advanced stages, granules are noticed scattered about in the grey substance which may have a different origin from that of the cell-debris.

Vessels.—Dilatation of both arterioles and capillaries is observed, similar to that in brain-wasting. Great caution is necessary in judging of such changes, as they may be owing to the preparative hardening process. There may be observed deposits of granules of a yellow colour and highly refractive, and crystals of hæmatin on the walls of the smaller vessels. The former are found scattered under the sheath of the vessels, or are collected in masses there, while the hæmatin-crystals are more frequently seen at the angles formed by the bifurcation of the vessels. The perivascular canals in this, as in many other forms of brain-disease, are enlarged, and the surrounding cerebral substance is coarse and indurated.

Fibres.—Loss of the branches of the cell is one of the first stages in atrophy; but the fibres throughout the whole of the grey matter are greatly altered, or even broken up, and their course very twisted and irregular. In this, as in other forms of long continued cerebral disease, they are decidedly coarser.

Neuroglia.—Wasting and atrophy are especially remarked. The fine and retiform aspect is lost, the disruption of structure presenting in the grey substance patches of molecules and nuclei. The nuclei are increased in number and assembled in groups, but without proliferation. In dealing with this almost new field of inquiry, in justice to Mr. Major, his conclusions are quoted in his own words.

‘*A. Cells.*—1. In senile atrophy of the brain the nerve-cells throughout the entire depth of the cortical layer, and in all parts, are morbidly affected, although to a variable extent and in a different manner.

‘2. In the large nerve-cells the morbid process in the great majority of cases is one of granular degeneration.

* ‘Observations on the Histology of the Morbid Brain.’ By Herbert Major, M.B. *West Riding Lunatic Asylum Medical Reports.* 1874.

'3. In the smaller nerve-cells generally, and occasionally also, but rarely, in the large, the process is one of simple atrophy, without granular degeneration, properly so called.

'4. The nuclei of the cells invariably participate in the diseased condition, and become the seats of granular deposits which lead ultimately to their destruction.

'5. At an early period the branches of the large cells are usually atrophied and destroyed to a greater or lesser extent, but exceptionally are retained up to a late period in the degeneration process.

'6. The condition of so-called hypertrophy of the cells (Rutherford, Tukey) depends on a peculiar transformation of some of the large pyramidal bodies, and is not confined to senile atrophy, being also observed in general paralysis, but in both is of exceptional occurrence.

'B. *Vessels*.—1. A condition of dilatation, both in the small vessels and in the capillaries, is that most commonly observed.

'2. Corresponding with this, there is enlargement of vascular canals with induration of the surrounding cerebral substance.

'3. As a rule, no great proliferation of the nuclei of the vessels is observed, the morbid deposits consisting of yellowish granules and hæmatin crystals, and there is no remarkable change in their course and direction.

'C. *Fibres*. 1. The fibres generally are abnormally coarse and tortuous, and in some instances seem to be broken down at various points.

'D. *Neuroglia*. 1. The most prominent change in neuroglia is one of atrophy and degeneration, the substance, at first loose and imperfect, breaking down ultimately into molecular *débris*.

'2. The neuroglia-corpuscles are somewhat increased in number, and, while at first presenting their usual characters, become eventually shrivelled and atrophied.'

Most wisely and cautiously Mr. Major introduces his paper by these warnings. '1. It may, nay more, it will, be found that many of the appearances I shall describe as being present in senile atrophy may be demonstrated with equal certainty and distinctness in other forms of cerebral disease. 2. I was driven to the conclusion, in the present as in previous inquiries, that, while in all cases I was able to discover decided pathological changes, yet, so far as my experience had gone, in none could I put my finger on any one point and mark it out as being constant and distinctive of the affection to the exclusion of all others; and to a great extent, as regards the cortical substance, further experience has only tended to confirm and strengthen this conclusion.' [These words are almost synonymous with those employed by the late Dr. Thomson Dickson. (*The Science and Practice of Medicine in Relation to Mind, etc.*) 'It will be long before we can isolate any set of cells, and say from definite appearances, "These are the cells of madness."'"] Lithographs illustrate the above described microscopical observations.

W. A. F. BROWNE, M.D.

ANATOMY AND PHYSIOLOGY.

ARLOING AND TRIPIER ON RECURRENT SENSIBILITY.—MM. Arloing and Tripier (*Gazette Hebdomadaire*, no. 36, 1874), publish the results of some new researches on recurrent sensibility, and suggest

applications of those results to pathology and operative treatment. The authors had previously sought to interpret the fact of the persistence of sensibility in the integument of the human hand after section of the median, radial and ulnar nerves, and had demonstrated the following points: the existence of recurrent sensibility in cutaneous nerves; the extension of the influence of sensory nerves of the skin beyond their zone of anatomical distribution, and that the persistence of sensibility in the peripheral extremity of the divided nerve, and the persistence of sensibility in the corresponding integument, are always associated phenomena. The exactitude of these data having been verified in the upper and lower extremities, the authors next proceeded to examine whether they were applicable to the nerves of the face. Analogous researches made on the chief branches of the trigeminal gave very variable results. They then commenced a series of experiments based upon the fact that the nerve-tubules are always found intact at the peripheral extremity when sensibility persists, and that, on the other hand, the tubules are degenerated when sensibility cannot be demonstrated. The researches were first made on the facial nerve of soliped animals, the peripheral extremity of which, according to M. Chauveau, is always found insensible, after section has been made below the parotid. Repeated experiments made by MM. Arloing and Tripier gave identical results, and on examination of the peripheral extremity all the nerve-tubules were found to be degenerated. In one case, where the section was made in front of the masseter muscle, compression of the peripheral extremity revealed doubtful sensibility; after a lapse of time, some intact fibres were found here. This result was due, the authors think, to the section having been made nearer the periphery. In order to prove whether this hypothesis was correct they instituted the following experiments. The inferior branch of the facial nerve of a mule having been exposed behind the labial commissure, the nerve was divided and its peripheral extremity isolated over an extent of two centimètres. At the end of two hours the peripheral extremity was again isolated, and when the nerve was more compressed the animal drew back its head and depressed forcibly the lower lip. Subsequent microscopical examination of hardened portions of the divided nerve showed about twelve intact nerve-tubules at the peripheral extremity, and about eight degenerated nerve-tubules at the central extremity. Experiments were next made on different branches of the trigeminal nerve in various animals. The authors assert that sensibility is very evident at the peripheral extremities of the supra-orbital and infra-orbital and the mental nerves of the dog after division. It is less evident in the supra-orbital and infra-orbital branches of the horse and rabbit, but is well marked in the mental nerve of those animals, a fact due to the more considerable number of intact nervous tubules at the peripheral extremity of the last-mentioned nerve.

In applying those experimental data to pathology and operative treatment the authors lay down the following propositions. 1. It being admitted that all nerves possess recurrent nerve-tubules, it may be supposed that special morbid conditions resulting from this anatomical disposition will present themselves equally in all nerves. Thus one may conceive the existence of neuralgiæ of the facial as of the trigeminal (the so-called functional neuralgiæ for

example). 2. Since, speaking generally, the recurrent fibres are the more numerous, the nearer one approaches to the periphery where the anastomoses are more numerous, whilst, as one approaches the main trunks, the fibres diminish in number and finally disappear, there ought to be marked differences in the mode of action, and the manifestations of the morbid agent, according as it affects the trunks or the periphery. The nearer the morbid agent is placed to the periphery, the greater the intensity and diffusion in its mode of action, and in the manifestations to which it will give rise; and on the other hand, the nearer the morbid agent to the trunk of the affected nerve, the less intense will be its mode of action and its manifestations. The authors hold with the majority of pathologists that, except in cases of compression, neuritis is very rare in neuralgia; they believe that it may arise from morbid changes in the proximal portions of nerves, but they do not think that it is absolutely necessary to admit these changes in any degree in order to explain the extension or diffusion of morbid phenomena, an exact notion of which may be formed by taking into account the peripheral anastomoses. The authors conclude that in the treatment of neuralgia the indications and operative proceedings ought to be much modified. Wishing to remain within the region of general considerations, they content themselves with these statements. 1. For motor-nerves or nerves supposed to be motor, the trunks in question ought not to be divided, but rather the neighbouring sensory branches which supply to the former recurrent nervous branches. 2. For sensori-motor or sensory nerves, it is necessary to find out whether the morbid agent affects the trunk or its branches. In the former case, simple neurotomy would suffice to interrupt the transmission of morbid impressions, whilst in the latter recourse should be taken to associated sections, made so as to interrupt the different modes of transmission, and at the same time cause the least possible disorder.

W. JOHNSON SMITH.

ROLLETT ON THE DIFFERENT EXCITABILITY OF FUNCTIONALLY DIFFERENT MUSCLES.—If a limb, with its muscles and nerves, be separated from the body, and fixed in a certain way, it will take a position of equilibrium dependent on the mode of fixation, and the weight and elasticity of the tissues. It will move out of this position, if the common nerve-stem be stimulated at some part of its course, and so the muscles be put in action. The new position of equilibrium will then depend on the action and counteraction of opposed muscles.

It has generally been supposed that the change of position of the limb in such experiments is in the direction of the opposing muscles, which exceed the others in mass. If this were the case, then stimuli of different strength applied to the nerve-stem should be followed by motion of the limb in the same direction; the amplitude only of the motion varying with the strength of the stimulus.

M. Rollett has, however, convinced himself by numerous experiments (*Wiener Akademische Anzeiger*), that this is not the case. He found that, with weak stimulation of the common nerve-stem, the limb was moved in quite a different direction from that obtained with strong stimulation.

This result was first established from three series of experiments (varying little from each other), made with the help of a stimulating apparatus, capable of fine gradations of strength. In a fourth series,

the same result was had for motor nerves still in connexion with the spinal cord, but removed from the influence of the brain and the sensitive nerves. In a fifth series, the fact was proved from a comparison of curves obtained simultaneously from antagonistic muscles, by a double myographion. Lastly, the fact was demonstrated, not with one determinate nerve-muscle apparatus only (muscles, in connection with their nerves, separated from the rest of the body), but with a series of different nerve-muscle apparatuses; for example: the motors of the foot forwards and upwards, and the motors of the foot backwards and downwards; the muscles which separate the toes, and those which bring them together; the muscles which draw the arm to the breast, and those which remove it; the muscles which bend the elbow, and those which straighten it. Of these muscles, the former-named antagonists had always the superiority with weaker stimulation of the common nerve-stem; the latter with stronger.

‘It remains to point out,’ says M. Rollett, ‘how important it is, if evidence is had, that in limb-masses loosed from all central connections, certain muscles of determinate function typically respond to less intensities of the stimulus applied to their common nerve-stem, than other muscles of different function.’

‘This fact must be taken into account in judging of a series of phenomena in which hitherto we have tended to consider exclusively the connection of the nerves with the central organs; for example, the variety of reflex motions following the same local application of a peripheric stimulus, where the strength of the latter is gradually increased, and in which at first the flexor, and later the extensor muscles have the inferiority; cramp after poisoning by strychnine, where the extensors prevail; several other remarkable forms of cramp; lastly, the mechanism of the co-ordinated movements (ordinated to an end), in general.

‘As regards explanation of the phenomenon, it must first be stated, that the muscular apparatus of a limb, after exclusion of the nerves, no longer shows this different behaviour in response to weak and strong stimuli. On symmetrical direct excitation of antagonistic muscles deprived of nerve-influence, the change of position of the limb is always in the direction of the muscles preponderating in mass, if both groups of muscles be kept perfectly capable of action. Thus the explanation of our phenomenon is to be sought in the nerves. We cannot, however, straightway conclude that nerves attached to different muscles have a different excitability. This would only be permissible if all other possibilities of explanation were excluded, or if evidence of an excitability varying in the section of the nerve-stem could be obtained by other metrical experiments. The latter has not hitherto been practicable. On the other hand, we have to consider the different form and number of the connections of different muscles with their motor nerves, and weigh the evidence of the phenomenon of difference in excitability being referable to this anatomical basis.’

ALEX. B. MACDOWALL.

HEYNOLD ON THE CONGLOMERATE GLANDS IN MAN.—Hans Heynold, a student of medicine in Leipzig, gives the results of his examinations of the various conglomerate glands in man (*Archiv für Pathologische Anatomie und Physiologie*, part 1, 1874). After distinguishing the efferent duct from

the coil itself, in common with other authors, he quotes Kölliker, to the effect that the commencement of the former is invariably narrower than the lumen in the coil itself, and continues so to its entrance into the Malpighian layer, where it dilates to about double the size, and, retaining this breadth, it traverses the epidermis. In the corium the sweat-glands always have a distinct cavity, and an external investment of connective tissue, with elongated nuclei, without smooth muscular fibres, and an epithelium of at least two layers of polygonal nucleated cells without pigment-granules, etc. After quoting the descriptions of the glands by Henle, Biesiadecki, Frey, Schrön, and Aufhammer, Heynold describes his own experiments. In order to examine the condition of the excretory duct, he used pieces of skin hardened in either two per cent. of bichromate of ammonia or in Müller's solution and afterwards in alcohol, and partly in one half per cent. of peroxide of osmium. The latter liquid was allowed to act for twenty-four to thirty-six hours, after which the pieces were placed in absolute alcohol. The following are the results of his investigations.

1. All secreting canals of the conglomerate glands are more or less provided with muscles.
2. All secreting canals possess (towards the lumen) a sharply demarcated cylinder-epithelium without cuticle.
3. All excretory ducts are devoid of smooth muscular fibres, and are invested with a cuboid epithelium of several strata, the innermost of which has a distinct cuticle.

As regards the glands of the axilla, the author arrived at the following results.

1. There exist in the axilla two different kinds of glands (axillary glands and sweat-glands).
2. The axillary glands are very large, and show a very strongly developed muscularity.
3. The epithelium of the axillary glands consists of one layer, is cuboid, shows a very broad cuticle, and is coloured brown by osmic acid.
4. The excretory ducts of the axillary glands have an epithelium of sometimes one or more layers, but the innermost stratum always possesses a cuticle. In the first case they sometimes possess muscles and are very wide; in the second case they are mostly narrow and without muscles.

H. A. REEVES.

DISEASES OF CHILDREN.

DESSAN ON THE DIARRHŒA OF CHILDREN.—The following observations by Dr. S. Henry Dessan are contributed to the *Southern Medical Record*. In cases of simple diarrhœa occurring in teething children, where there is no fever, and there is absence of pain on pressure over the abdomen, where the stools are more frequent, thinner and copious than usual, when the cause is presumed to be nothing more than the highly irritable state of the nervous system, the effect of the transitional process of teething, and reflecting its action on the alimentary canal; if the gums should be found swollen, red and tender, they would be lanced; but since my term of service at the dispensary, I have never found occasion to lance a gum. I generally, in such cases, administer a sedative, such as the bromide of potassium, in doses of two to four grains every three hours, and insist upon careful attention to the

diet of the child. If an astringent be found necessary, I give

R. Misturæ cretæ . . . fl. 3j
Tinct. catechu,
Tinct. opii camph. . . aa gtts. iv

every three hours. When the patient has acquired a mixed dietary and presents the same symptoms of simple diarrhœa as before mentioned, the cause being due to eating improper food, if seen shortly after the commencement of the attack,

R. Olei ricini,
Syr. rhei aromatici . . . aa fl. 3ss
Sodæ bicarbonatis . . . grs. ij.—M.

is ordered to be taken every half hour until the bowels have been freely evacuated, and afterwards to be taken twice or three times daily. This mixture is similar to the Chaussier mixture, with the exception of the soda, which is added as an antacid. Stillé, in his work on *Materia Medica*, remarks of castor-oil, that it is peculiarly adapted to the diarrhœas of children from causes as at present under consideration; because, while it impresses the general system very slightly, it has a sensitive influence upon the bowels themselves.

In cases of simple diarrhœa occurring in children who have completed the first dentition, where there appears to be a lack of tone in the digestive organs, and where the stools present the condition of lientery, a tonic of sulphate of quinine and tincture of chloride of iron is given, together with eight to ten grains of pepsin, taken with the food at meal-time. Pepsin is also given in those cases of simple diarrhœa, in growing children, where the stools are large, watery, frothy and of fetid odour.

Where simple diarrhœa is met with in strumous children, I administer the following:—

R. Olei morrhuæ . . . 3iij
Syr. pruni virginianæ,
Liquoris calcis . . . aa 5j.—M.

The lime-water acts as an emulsifier, and the wild cherry renders the oil more tolerant to the stomach, and at the same time serves to disguise its taste. I have always found the oil to be easily digested after continuing its use for several days, and the looseness of the bowels to gradually disappear without further treatment. When change of temperature, commonly termed cold, is the cause of the diarrhœa, by some writers styled intestinal catarrh, the following mixture:

R. Tinct. opii camph. . . gtts. iv
Extracti ipeacacianhæ . . fl. gtt. 4.—M.

given in a teaspoonful of equal parts of syrup and water, is prescribed for infants, and larger doses for older children. The castor-oil mixture answers fully as well in such cases, and is more frequently given than the first-mentioned combination.

I now come to the consideration and treatment of that variety of the intestinal disorders of children that is by far the most frequently met with by the profession, in any portion of America. It is the summer complaint, by some confounded with cholera infantum, but which I, following the able distinction made by our American authorities, Meigs and Pepper, will term entero-colitis, or inflammatory diarrhœa of children.

When this form of diarrhœa presents itself to my notice, appearing in a child undergoing dentition, where the evacuations are frequent and present the familiar green or chopped spinach appearance (which, according to such high authority as Cham-

bers, is due to nothing more nor less than blood which has undergone transformation), and also containing mucus and undigested curd, all more or less certain indications of inflammatory destruction; and when, moreover, during the first days of the complaint, it is attended with marked fever and tenderness upon pressure over the abdomen, and more especially in the region of the iliac fossæ, I at once place the little sufferer upon a genuine antiphlogistic treatment. The following dose is given in a teaspoonful of dill water :

R. Liquoris ammoniæ acetatis, vel
Liquoris potassæ citratis . . . gttss. xx
Tinct. opii camph. gttss. iv.-x
Extracti ipecacuanhæ . . . fl. gtt 1-½

I order the diet to be carefully regulated, the breast to be given not oftener than every three hours, and if there be much vomiting, teaspoonful doses of toast-water containing ice to be given. In cases where vomiting appears as the principal symptom, I am in the habit of giving the following :

R. Hydrarg. chlor. mit. . . . gr. j
Sacchari albi gr. xv.—M.

To be divided into sixteen powders: one to be given every two hours.

When the disease has progressed for several days, until the febrile symptoms have subsided, or where such changes appear in the evacuations as before remarked, following a previous simple diarrhœa, I employ the following powder :

R. Pulveris rhei gr. vj
Pulveris ipecac. comp. . . . grs. x
Sodæ bicarbonatis grs. xij.—M.

To be divided into twelve powders: one to be given every three hours to a child under one year of age.

I also sometimes use the following, for the same age.

R. Vini ipecacuanhæ gttss. ij
Tincturæ calumbæ gttss. xx
Misturæ salinæ 3 ij.—M.

To be given every three hours.

The saline mixture is made by adding lemon-juice in sufficient quantity to neutralise twenty grains of carbonate of potassa dissolved in an ounce of water. (The composition of the prescription is due to Pavy.) In addition to drugs and attention to diet, I generally recommend a hot bath to be given twice daily, and the baby to be wrapped in a blanket, after being dried, so as to invite free perspiration. Plenty of fresh air is advised, which is especially necessary in a large city like New York.

When this variety of diarrhœa presents itself in children over a year old, and in those under that age also where there are streaks of unaltered blood in the stools, I use the following :

R. Bismuthi subnitratiss 3 j
Pulv. ipecac. comp. gr. xx
Pulveris zinziberis grs. iijj.—M.

To be divided into twelve powders: one to be given every three or four hours.

The bismuth also serves to quiet the stomach where there is much irritability present. When the stools contain undigested matter, I give, in addition to the above, eight to ten grains of pepsin three times daily.

Where the disease has lasted for several months, and has assumed all the features of a chronic diarrhœa, whether the patient has completed dentition or not, I give the cod-liver oil mixture before men-

tioned in the proportion of four-and-a-half ounces to half an ounce of syrup of iodide of iron, a teaspoonful of which is to be given three times daily. It acts in the same beautiful and pleasing manner as in the simple diarrhœa of strumous children. Indeed, there is an analogy between the two affections, as in both the mesenteric glands are enlarged, and these, no doubt, are important factors in the chronicity of the disease. I have sometimes advised the raw beef diet to be used in chronic diarrhœa, but it has been more from wishing to vary my practice than from any want of confidence in the cod-liver oil and syrup of the iodide of iron.

BYRD ON CHOLERA INFANTUM.—Dr. Harvey L. Byrd writes as follows in the *Philadelphia Medical Times*. This terrible scourge of infancy and childhood is carrying large numbers of the young and tender ones of this community to their long homes, and such is the extent of its ravages that it might be said with propriety of language to prevail at this time as an epidemic in our midst.

Baltimore, hygienically considered, is probably equal in all, or at least very many, respects to her most favoured sister-cities; but, while this is the case, the hand of the destroyer occasionally falls heavily upon her, and she is then called upon to mourn the loss of those she cannot rescue from the embrace of death. Since the event of summer the mortality has been considerable among infants and children one to three and four years old, but it is chiefly within the last three weeks that our mortuary tables exhibit a fearfully large proportion of death from cholera infantum. Within this period there has been not only a steady but an alarming increase in the death-statistics from this generally intractable and fatal malady. After resorting to the remedies most in vogue in the treatment of summer-complaint, such as calomel in minute and moderately large doses, alone and in combination with Dover's powder, chalk, charcoal, etc., bismuth, magnesia, pepsin, tannic and gallic acids, acetate of lead, alum, nitrate of silver, creasote, pyroligneous acid, laudanum, etc., alone and in various combinations and mixtures with indifferent or unsatisfactory results, even when strict attention was given to diet, fresh air, bathing, stimulants when called for, etc., it was finally decided to adopt a plan of treatment with special reference to an alterative action on the blood; at the same time giving strict attention to the skin with a view to the elimination of the poison, as far as might be, by this organ.

Accordingly, with the leading object in view, namely, an appeal to the blood primarily, sulphite of sodium and aromatic sulphuric acid were prescribed internally, and tepid or cold alkaline baths, according to indications, ordered externally, to which whiskey or brandy was added when required.

One grain of the sulphite, with four drops of paregoric, was given in gum-water every two hours, to a child one year old, and the dose doubled for a child two years old, increasing or lessening it according to age and the anodyne effects of the paregoric, thus :—

R. Sulphite of sodium grs. xvj
Powdered acacia grs. xij
Camphorated tincture of opium . fl 3 j
Water 3ij.—M.

Sig.—One teaspoonful every two hours, to a child one year old, shaking the phial before using. One drop of elixir of vitriol in three spoonfuls of iced water was given, three times a day, to a child one year old;

and the dose was increased one drop for each year, and lessened to one-fourth or one half-drop when below one year of age. A tepid or cold bath, rendered alkaline with an ounce or more of carbonate of sodium, or potassium, or common salt, was used morning and night. In addition to the foregoing remedies, aromatic cataplasms were ordered, and kept applied over the entire stomach and abdomen. Cow's milk and farinaceous articles of food were not allowed, and scraped or finely chopped beef, or lamb, raw or but partially cooked, or essence of beef (to which a small portion of brandy was added when required by the feebleness or prostration of the patient), was used as much as practicable as nourishment. Wine-weigh was allowed freely in the second stage of the disease, when it agreed with the patient. Infants were allowed the mother's milk, or that of a healthy wet-nurse, and fifteen to twenty drops of lime-water three or four times a day when the milk disagreed. This plan of treatment has been pursued for the past two weeks, with complete success. In a small proportion of cases, quinine, in appropriate doses, was also administered when a tendency to periodicity was observed.

RAUTENBURG ON PNEUMONIA IN CHILDHOOD. Dr. Rautenburg, of St. Petersburg, sends a preliminary contribution, upon pneumonia in childhood, to the number of the *Jahrbuch für Kinderheilkunde* for September 18, 1874. In the ensuing numbers he will give the facts which have led him to the following conclusions. 1. The distinction of croupal and catarrhal forms of pneumonia in childhood is justified neither by microscopical nor by macroscopical examinations of the dead body, nor by the course of the disease during life. 2. The designation of lobar pneumonia as croupal, and lobular as catarrhal, must be looked upon as incorrect. 3. We may speak only of greater or smaller pneumonic masses, and not of lobar and lobular pneumonia. 4. Inflammation of the lung essentially consists in a lesion of tissue, not yet sufficiently examined, which leads to the exudation of leucocytes from the blood-vessels into the pulmonary alveoli, and to further metamorphoses of the extravasated corpuscles. 5. The admixture of fibrin with the exudation which occurs in inflammation of the lungs is not essential and characteristic, but must be looked upon as accidental, and determined, not by the form of the inflammation, but by conditions yet unknown to us, perhaps by peculiarities of epidemic, individual, or excitant of the inflammation. 6. The chief stress in the distinction of the forms of pneumonia must be put upon the etiological momentum of it. This plays the chief part in determining the course and consequences of the inflammation of the lung. The pneumonia of children may arise either spontaneously, from changes in the weather, and attacking otherwise healthy subjects, which in children is the less common case, the course of the disease being eminently cyclic, and ending for the most part favourably; or, as a result of other conditions which predispose to tissue changes in the alveoli. These conditions are: progressive bronchial catarrh, blockage of the finer air-tubes by plugs of mucus, foreign bodies, etc., and general debility causing imperfect expansion of the lungs. To the last class belongs pneumonia coming on in chronic diarrhoea, chronic suppuration, etc., and hastening death. Hence two forms of inflammation of the lungs may be distinguished, the genuine and the secondary. Genuine

pneumonia, without being always croupal and lobar, yet answers to these in its violent and cyclic course; secondary pneumonia ranks itself with catarrhal pneumonia in its course, without being identical. This distinction holds good not only in the appearances before and after death, but also in therapeutics; genuine pneumonia requiring an expectant method of treating symptoms, whilst tonic and stimulant means must be employed against the secondary form.

HÜTTENBRENNER ON CATHETERISING THE LARYNX IN CROUP AND DIPHTHERIA.—Dr. And. v. Hüttenbrenner (*Jahrbuch für Kinderheilkunde*, September 18, 1874), after just making mention of Loiseau, and of Bouchut's 'tubage de la glotte,' passes on to criticise the method set forth by Weinlechner (in the same year-book for 1870, p. 69.) The opinions of Hüttenbrenner are thus summed up.

1. Upon the passage of a catheter, or of Weinlechner's pipe, into the larynx, the child may become accidentally asphyxiated. This accident is due either to a great difficulty in passing the tube, when the operator has not the help of two or three people to hold the struggling child; or to separation of false membrane from the glottis, and aspiration of the same into the trachea on the bifurcation of the bronchi. The latter accident has happened twice to the author.

2. Repeated catheterism, upon every recurrent narrowing of the larynx, is harmful; by no means making tracheotomy unnecessary in the long run, and greatly exhausting the child's strength.

3. Wounds of the mucous membrane of the mouth and cheek, by the gag, can hardly be helped. Moreover, the glottidean pipe easily scrapes the larynx; the abrasions bleed at the time, and are covered with false membrane in a few hours.

4. The relief after catheterism does not last more than a few hours, and then the child is left as bad as before.

5. The operator needs the help of several experts, and hence can hardly undertake the operation in private practice, without running great risks.

6. There is only one indication for the use of the laryngeal catheter in croup, and that is, when life is threatened, to gain time for tracheotomy.

SAMUEL GEE, M.D.

GRANGÉ ON THE SYMPTOMS OF TUBERCULISATION IN CHILDREN AND THEIR SEMEIOLOGICAL VALUE.—Dr. J. Grangé (*Thèse de Paris*, abstracted in *Revue des Sciences Médicales*, 1874), has sought to define more clearly than has as yet been done, the exact physiognomy of tuberculous children; as well as the importance of the various symptoms presented in them. Unfortunately tuberculosis shows itself under so many forms, is so common during infancy, and develops itself in so different a manner, according to the parts most directly attacked, that it is difficult to give a connected account of symptoms which differ widely. After describing the signs afforded by examination of the thorax, the respiratory movements, and the dyspnoea, Dr. Grangé proceeds to study the fever of tuberculosis. He points out the marked variations of the thermal curve, according as the inflammatory phenomena advance more or less rapidly; but whatever may be the character of the phthisis, it is thermometrically distinguished by the amplitude of its daily oscillations, and the great difference between the morning and

evening temperatures. On the contrary, tuberculation of the peritoneum causes but a slight increase of temperature; indeed, when it is unattended by complications of an inflammatory nature, the temperature is lowered. In meningeal tuberculosis the temperature is very low at the stage when the phenomena of cerebral depression become manifest. The thermometer may indicate important differential signs in cases where the presence of typhoid fever might be supposed. Dr. Grangé then proceeds to study carefully the symptoms of pain, vomiting, and disturbance of the cutaneous and secretory functions; but as these symptoms differ but slightly from the corresponding disorders from which adult phthisical patients suffer, and as their very diversity is unfavourable for generalisation, there is nothing striking or original in this section of his researches. This treatise contains a useful series of tracings of thermic waves taken from tuberculous children, and a considerable number of notes of cases; among which some, taken with great care, relate to cases of cerebral tuberculosis and tuberculous meningitis.

E. LAWSON.

SURGERY.

SCHNEIDER ON EXTIRPATION OF THE SCAPULA. Dr. R. Schneider, of Königsberg, reports a case (*Berliner Klinische Wochenschrift*, no. 31, 1874), in which the left scapula was extirpated on account of a sarcomatous tumour. The subject was a weakly boy, aged six and a half years. The tumour had been growing for five months, and during the last three months had increased rapidly in size. The whole of the left scapular region was finally occupied by a firm elastic painless growth, closely connected with the bone, but not involving the integument. This growth was of the size of the fist, and internally terminated at the base of the scapula, but passed beyond the external and superior margins of the bone. It occupied the whole of the outer surface of the bone, filling the supraspinous and infraspinous fossæ, and sent out a modulated outgrowth into the axilla. The action of the left arm was much impeded. No swelling of the corresponding lymph-glands could be made out. On account of this, and of the slow growth, and the yielding consistence of the tumour, Dr. Schneider regarded the affection as sarcoma of the scapula. On December 3, 1873, the whole of the diseased bone was excised. The first incision was made along the base of the scapula; the second was commenced at the acromion and carried horizontally along the upper margin of the tumour to the commencement of the first incision. A flap was thus formed, the free apex of which corresponded to the upper and inner angle of the scapula. The portion of tumour which projected beyond the upper margin of the bone was then exposed. The muscles attached to the inner and outer margins of the scapula were next divided. As the acromion, the neck of the scapula, and the acromial part of the clavicle had become involved in the tumour, it was found necessary both to open the shoulder-joint and to remove a portion of the clavicle. The deltoid muscle was cut through at its upper part, and the clavicle exposed and divided at an apparently healthy part. The articular capsule was now exposed, and the long tendon of the biceps muscles, and the tendons of the muscles inserted into the great and small tuberosities, were cut through. The

articular capsule was then completely separated from the margin of the glenoid cavity. The axillary portion of the tumour was dissected out with great care, in order to avoid wounding any of the large vessels of this region. The tendons of the muscles attached to the coracoid process having next been dissected, the separation of the tumour from the side of the thorax was easily effected. The supraspinatus, infraspinatus, and subscapularis muscles were wholly removed. During the operation, the subclavian artery was compressed against the first rib. A spray of carbolic-acid solution was played upon the wound during the operation. The vessels were closed by carbolised catgut, and the dressings were strictly according to Lister's plan. The operation lasted for little more than half an hour, and the hæmorrhage was very slight; consequently there was no subsequent collapse. The boy did well from the sixth day after the operation, and on January 26, 1874, was regarded as cured. At this date the parts about the seat of operation were quite sound; the left shoulder was somewhat more depressed and less rounded than the right. The outer extremity of the clavicle, on which was fixed the head of the humerus, was directed backwards. The left arm was as large as the right. The left arm could not be abducted to any great extent, though by passive movement it could be easily elevated to the horizontal position. The humerus could hardly be moved, either forwards or backwards. The hand could be raised to the mouth and occiput through the free movement of the fore-arm.

On subsequent microscopical examination, the tumour presented the structure of a lymph or granulation sarcoma, which had undoubtedly been developed between the periosteum and the surface of the bone. The main elements were small ovoid cells filled with glistening protoplasm. The basis substance in the intraperiosteal portions of the growth was very delicate and soft, and on the extraperiosteal portions tough and fibrillated. In the course of a few weeks after the operation the disease returned in the left shoulder, near the cicatrix, and at the same time a diffuse, doughy, and painful tumour appeared at the upper part of the right tibia. These growths increased rapidly in size, and the patient's general health became much impaired. On April 20th he succumbed, death having been preceded for some weeks by pain in the back, great prostration, and paralysis of the bladder and lower limbs. At the *post mortem* examination secondary growths were found in the lungs, on the anterior surfaces of the fourth and sixth dorsal vertebrae, and on the posterior surface of the sixth dorsal vertebra. The deposit in the last-mentioned situation had considerably contracted the calibre of the vertebral canal.

Dr. Schneider states that this is the nineteenth reported case of excision of the scapula, with preservation of the upper limb. The whole scapula, with the exception of the coracoid process, was first removed by Von Langenbeck in 1850, and the whole bone, together with a portion of the clavicle, was extirpated by the same surgeon in 1855. The scapula has been removed in two cases on account of caries, once on account of some obscure tumour, three times on account of enchondroma, once on account of an osteo-fibroid growth, and in thirteen cases on account of sarcoma or carcinoma. Of the nineteen subjects of these operations one only died from the immediate effects. Two patients died from pyæmia, and one in consequence of bronchitis. In one case the disease

returned in the wound made in the operation, and the patient speedily died. The remaining patients recovered from the effects of the operation, and were at least temporarily cured. Dr. Schneider holds that the risks are smaller with total than with partial removal of the scapula. The hæmorrhage during the former operation is not very formidable, if the subclavian artery be compressed.

HEIBERG ON A NEW METHOD OF TREATING DANGEROUS SYMPTOMS PRESENTED DURING THE ADMINISTRATION OF CHLOROFORM.—Dr. Jacob Heiberg of Christiania (*Berliner Klinische Wochenschrift*, no. 36, 1874), describes certain manipulations for the relief and removal of disquieting symptoms often presented during the administration of chloroform. These consist especially in noisy and retarded respiration, congestion or pallor of the face, and a small pulse. This condition, frequently met with in hospital practice, is usually treated by forcible separation of the jaws, and by dragging the tongue forwards with large forceps or sharp hooks. To these proceedings the author raises the objections that they interfere with the course of the operation and distract the attention of the surgeon; that the tongue is often wounded by broken or sharp teeth; and thirdly, that the quantity of chloroform used is often necessarily increased, and the subsequent ill effects of the narcosis rendered more intense. The manipulative proceeding, recommended by the author, consists in depressing the lower jaw *in toto*. When the respiration becomes noisy and disturbed, and in all cases where hitherto the teeth have been separated and the tongue pulled forwards, Dr. Heiberg would depress the jaw in the following manner. The chloroformist, standing behind the recumbent patient, places both thumbs on the symphysis of the lower jaw, passes the second segment of the flexed index finger behind the posterior margin of the ascending ramus of the lower jaw on each side so as thus to hold fast the whole bone between both hands, and then with some force drags the jaw directly forwards. The whole jaw may thus be made to glide forwards, so that the lower dental arch stands in front of the upper arch. This proceeding, which may be carried out with special facility in children, is at once followed by deep and perfect respiration. So long as the jaw remains dislocated, so to speak, respiration is unimpeded and quiet, and just the same result is obtained as from traction on the tongue. Dr. Heiberg states that the anatomical reason for this favourable result is not quite clear to him, but he thinks it probable that the epiglottis lying over the rima glottidis may be thus elevated. The following are supposed to be the chief advantages of Dr. Heiberg's proceeding. 1. The operator can do his own work with less disturbance, and the operation can be performed quietly and with more safety. 2. Lesions of the teeth and tongue are thus avoided. 3. Less chloroform is used, the after-effects of the narcosis and the dangers of chloroformisation being thus lessened.

W. JOHNSON SMITH.

CHIENE AND MAUNDER ON SUBCUTANEOUS FRACTURE OF EXOSTOSIS OF THE FEMUR.—In the *Edinburgh Medical Journal* for July, Dr. Chiene, *à propos* of a case under his own care, asks the question, 'Is an exostosis, after it is broken off by violence, ever absorbed?' A boy aged fourteen was brought to Dr. Chiene, in April, 1873, with a hard movable tumour under the muscles of the thigh, above the

inner condyle of the right femur; with a history that it was first known to him twelve months previously, when, after recovery from a blow on the inner side of the knee, which had caused swelling and pain, and some inability to bend the joint, he found a hard lump, which he could move backwards and forwards. When he was first seen by Dr. Chiene, there was an irregular osseous mass, freely movable, of the size and shape of a walnut, under the vastus internus, two inches above the condyle. When moved, it rubbed against an osseous surface on the femur, but the feeling of crepitus, although perfectly distinct, was somewhat modified, as if the opposing surfaces were covered by fibro-cartilaginous material. Soreness after violent exercise or free manipulation of the tumour was the only thing complained of; and Dr. Chiene recommended delay before the removal of the detached exostosis, in the hope that its absorption might follow the cutting off of its principal blood-supply. From this date the tumour gradually lessened; in October the boy could feel nothing; and in April of the present year, with the exception of a slight linear projection an inch in length, on the osseous ridge, leading up from and about two inches above the internal condyle, Dr. Chiene could not distinguish any difference between the limbs. The result of this case suggests to Dr. Chiene the advisability, in the treatment of exostosis, of attempting in the first place to break off the exostosis subcutaneously, by laying hold of it with large forceps, well padded so as to prevent injury of the skin, in the hope that absorption of the tumour will take place in consequence of the loss of blood-supply; and, secondly, that in such a case as his own the surgeon should wait, and not hastily cut down on the tumour to remove it.

The August number of the same journal contains a preliminary notice from Mr. Maunder of a case under his care in the London Hospital. He had in June discussed the possible methods of treatment—subcutaneous fracture, subcutaneous section by chisel and mallet, and by free incision; and on July 8 he was able, under chloroform, to determine that the globular head of the growth was attached by a slender stem to the outside and back of the femur near to the knee-joint. This pedicle was fractured with comparative ease with a large pair of pliers, and with a jerk, the skin being protected with a piece of chamois leather. Some swelling and ecchymosis followed this operation, the result of which is not yet made known.

[Subcutaneous absorption must be a much preferable and infinitely safer method for the removal of exostosis, than that by free incision, an operation bordering often closely on the knee-joint. Accidental fracture of the stem of an exostosis of the femur, when the stem is slender, is not unknown; and it would be well in all such cases to adopt the suggestion of Dr. Chiene, and defer operating, with the hope of ultimate absorption of the tumour. We shall be interested to know the end of Mr. Maunder's case of artificial detachment of the exostosis.—*Rep.*]

HERBERT PAGE.

SYPHILOGRAPHY.

LACOMBE ON HEPATIC SYPHILIS IN THE ADULT. Hepatic syphilis, as M. Lacombe observes (*Progrès Médical*), is at once an old and a new question. It is old in fact, for the medical men who came after the Renaissance attributed to the liver, which played a pro-

minent part in the vital functions, the seat of a disease which exercised so serious an influence over the animal economy; and yet new, since really scientific researches on syphilis only date from about twenty-five years since. Dittich's first memoir only appeared in 1849, and subsequent researches but serve to consolidate and complete the work of the physician of Prague. A considerable number of medical men, however, in France and other countries, have added their stone to the general edifice. Gubler in 1852, Quetelet in 1856, Lecontour and Virchow in 1858, Leudet in 1860, Lancereaux, Cornil, and Ranvier, have brought to light all the variety and capriciousness belonging to the clinical and anatomic-pathological manifestations of this disease. In the anatomical portion of his work, M. Lacombe recognises and describes two principal forms in lesions of the liver, interstitial hepatitis, and gummatous hepatitis, of which he gives the histological description in detail, from the works of MM. Lancereaux, Cornil, Ranvier, and Hayem, afterwards going into an interesting discussion on the unity or duality of the sympathetic lesions of the liver. We know, in fact, that the generality of writers consider interstitial hepatitis and gummatous hepatitis to be of totally different orders; the first they hold to be of a purely inflammatory nature, whilst the second alone is markedly a specific disease. M. Lacombe is of a different opinion, and believes that the anatomical nature of the lesions is identical, all the difference between them arising from the fact that they do not attain to the same degree of evolution. The question is, at what stage of syphilis hepatic lesions appear. It is difficult to solve this question in a general way, for syphilis of the liver is often latent, sometimes is only found out on necropsy, and may last a long time without betraying its existence; whence the difficulty. It does not appear possible to say whether, as some writers think, the diffuse lesions are always primary, and the circumscribed lesions, the gummata, are always consecutive.

In a second and clinical portion of his work, M. Lacombe traces the symptomological history of hepatic syphilis, and includes a number of unreported cases collected by him in the hospitals, or given to him by his colleagues, MM. Rendu, Troisier, Homolle, Raymond, etc. A certain number of these cases gain special value from microscopic examination, generally made by M. Hayem, who even describes a lesion not pointed out before he did so, and which he calls perilymphangitis; the meaning of this term being that the lymphatics have increased in number, and that many of them are dilated and surrounded, as it were, with a ring of connective tissue. The concluding chapters of this valuable monograph relate to the icterus of secondary eruptions. They inquire into the nature of that icterus to which M. Gubler specially drew the attention of the profession in 1853; whether they depend on syphilis, and by what mechanism they are produced. The influence of syphilis on the development of icterus is scarcely to be contested at the present day, for observation has sufficiently proved that that icterus is etiologically connected with syphilitic manifestations. The author passes in review all the opinions hitherto enumerated concerning the mechanism by which it is produced, and takes his stand on that which pronounces that the icterus which is coincident with premature syphilitic eruptions is a simple catarrhal icterus, only differing by its cause from the more ordinary catarrhal icterus.

OBSTETRICS AND GYNÆCOLOGY.

BANDL ON A CASE OF EXTRAUTERINE PREGNANCY.—Dr. Ludwig Bandl reports in the *Wiener Medizinische Wochenschrift* of August 8, a case of extrauterine foetation occurring in the practice of Professor Karl Braun-Fernwald, in which rupture of the ovum took place at an early period of pregnancy, and the embryo arrived at full maturity in the cavity of the abdomen.

According to Hecker and Cauwenberghe, ovarian and tubular pregnancies generally terminate fatally both to mother and foetus about the third or fourth month, through rupture of the ovum. In abdominal pregnancy (extra-uterine) this accident often does not occur until towards the end of gestation. The foetus generally dies forthwith, and it is only in very rare instances that the ovum develops and lives in the abdominal cavity (*graviditas extra-uterina secundaria*). Most gynæcologists are incredulous of this form of foetation. Schröder says that there is no doubt that a foetus in this condition, as it becomes encapsuled by new inflammatory exudations can live but for a short time. Only one similar published case to that now reported has been found by the author (Walter, *Monatsschrift für Geburtskunde*, vol. xviii.). The present one occurred in a woman aged thirty-five, mother of two children. Each previous confinement was natural. She was admitted on Nov. 20, 1871, into the hospital in a wretched condition. She menstruated last at the beginning of April. During the first two months of gestation she was quite well; since then she had been in continual pain, and had become greatly emaciated. On admission the abdomen was distended, resonant over its whole surface, with distinct fluctuation. The foetus could be easily made out, and its heart-sounds heard. *Per vaginam*, the os was found to be as high as the arch of the pubes, and was only reached with difficulty. It was soft and patulous, admitting two phalanges of the forefinger. The foetus could not be felt; but by bimanual examination the body of the uterus was made out to lie in the left side, and in the right iliac fossa, and stretching into the pelvic cavity an elastic swelling. Extra-uterine foetation was diagnosed. The uterine sound was used three days afterwards, and passed four inches to the left. With a delicate movement of the sound towards the right, it was made to pass nine inches, and its point could be easily felt beneath the thin abdominal walls in the neighbourhood of the umbilicus. This passage of the sound made the diagnosis of extra-uterine foetation somewhat doubtful. The sound had either passed into the gravid uterus or into the dilated cavity of an uterus bicornis or duplex, or there might be an intra-uterine pregnancy along with the extra-uterine. Perhaps the uterus had been perforated or the sound had slipped up the Fallopian tube. Although Matthews, Duncan, Veil, and Hildebrand, maintain the possibility of the uterine sound passing into the Fallopian tube, still, judging from experiments on the dead body, Dr. Bandl thinks it scarcely credible. He believes with König, that in all these instances there has really been perforation of the uterine walls. The puerperal uterus is readily perforated by a slight pressure of the sound; and that organ in extra-uterine foetation is in a similar condition. The writer states that he has in several cases perforated the uterus in the dead subject with the sound with-

out using any force, in women who have died during the puerperal state. Alt's experience is the same. Martin reports a case where, some months after parturition, on laying open the abdomen, the point of the sound was found sticking through the walls of the uterus. In the above case it was therefore very probable that the instrument had perforated the uterus.

On November 29 Professor Braun held a consultation with Professors Späth and Professor G. Braun on the case. The sound had failed to give any assistance in ascertaining the nature of the swelling lying to the right in the abdomen; nor did it exclude the idea of an uterine pregnancy, or of a foetus in the right half of an uterus duplex. The body felt in the right iliac region might be either the placenta, a tumour, or an ovarian cyst. The woman having been anæsthetised, the sound again passed the ten inches in the same direction as before. With the hand in the vagina the fore-finger could be passed easily inside the uterus, and the fundus could be easily pressed down from without on the finger. Nowhere could any opening be felt indicating a double uterus. The swelling on the right side from its shape and consistence was believed to be an ovarian cyst, about the size of a foetal head. During the examination two pieces of decidua, each about a square inch in size, came away. The foetus was made out to be about seven pounds in weight. The patient would not submit to any operation. The next day feverish symptoms set in, and on the fourth day she suddenly collapsed and died. A living child weighing eight and a quarter pounds was removed by abdominal section five minutes after death, but it only lived ten minutes. Six to eight pints of fluid escaped at the moment of opening the abdomen, but no portion of foetal membranes could be found.

Dr. Kundrat on the next day made a necropsy. The organs of the head and chest were normal. There were five or six pints of turbid serous fluid in the peritoneal cavity. The omentum was adherent, and the anterior walls and the peritoneum were injected, and covered with a deposit of loose false membrane. On removal of the small intestines the cavity in which the foetus had lain was apparent. The anterior and lateral walls were formed of a thick false membrane, two or three lines thick, covering the abdominal parietes. The posterior and superior walls were formed slightly by the posterior abdominal parietes, but chiefly by the small intestines, which were connected by membranous bands, and by the ascending and descending colon. The inferior wall was made up partly of a tumour, and partly of the various pelvic organs bound together. There were numerous fibrinous bands stretching across from one side of this cavity to the other. The uterus lay to the left; it was five inches long, and close to the orifice of the left Fallopian tube was the spot through which the sound had penetrated. The left ovary was of normal size; the right was reduced one half, and, with the right Fallopian tube, was bound down to a swelling six inches long, five wide, and four thick, lying partly on the right iliac fossa and partly on the pelvis, and united to the posterior abdominal wall by thick false membranes. This tumour contained the placenta. The walls of the tumour consisted of firm strong layers, three or four lines thick. Opposite the uterus there was a small round opening, with a sharp margin about an inch across, through which the cord passed from the placenta to the foetus. It was wound round the uterus and

slightly attached to it. From the opening, brownish-yellow wrinkled foetal membranes, evidently belonging to an earlier stage of pregnancy, bulged out around the umbilical cord. The walls of the tumour in which the placenta was were quite smooth to the touch.

From this condition of things there can be no doubt that the ovum burst at an early period of pregnancy into the peritoneal cavity. The extraordinary part is, that with the exception of continuous pain and gradual emaciation, the woman never had a day's illness. The rupture took place most probably about the third month. The tumour was nourished by branches from the iliac arteries. The distal end of the right Fallopian tube was intimately connected with the tumour. Whether it was a tubar or tubo-abdominal pregnancy could not be distinctly made out.

BAILLY ON UTERINE SOUFFLE AFTER CONFINEMENT.—In instituting researches into this physiological phenomenon, M. Bailly (*Archives de Toxicologie*, 1874), has been actuated by a desire to see what effect the process of involution had on its frequency, its tone, its intensity, its duration, etc.; its practical application may not as yet be apparent, and its importance he in no way wishes to exaggerate.

Frequency.—He made observations upon seventy-eight women, taken promiscuously amongst the patients. A bruit was discoverable sixty-eight times, or in the proportion of 87.1 per cent. Amongst *enceinte* women, M. Depaul found that it existed in about 95 per cent. of the cases examined. It is, therefore, rather less frequent than Depaul thought.

Character.—In the large majority of instances the tone was soft, liquid, and prolonged, not unlike the sound of the syllable *vous*, when spoken slowly by a bass voice; it is always intermittent, and its duration is longer than the pause. The *bruit de diable*, so frequently heard during pregnancy, was not once observed. The *intensity* is about the same as the souffle heard between the fourth and fifth month of pregnancy. Three or four times it was as loud on the morrow of the confinement, as at the end of pregnancy. The larger the uterus, the louder the sound.

The chief difference in the souffle in the *enceinte* woman and the puerperal woman consists in the tone of the latter being of less volume, less lasting, and less strong. The sibilant, musical, and rough notes, often heard in the pregnant woman, are very rare in the other.

The sound is generally heard over the sides or over the lower half of the uterus, rarely over the superior moiety. It predominates on the left side; out of fifty-eight cases it was found of equal intensity on both sides fifteen times, stronger on the right thirteen, and on the left twenty-six times. The position of the uterus did not alter the ratio.

Progress and Termination.—There is an intimate connection between the subsidence of the uterus and the disappearance of the bruit. In the majority of cases it disappears when the uterus is about 11 or 12 centimètres above the symphysis pubis, but in some cases it has been observed to vanish when the womb was 14 or 15 centimètres above the pubes, and to exist when it was 8 to 10 centimètres, and that two or three days after labour.

Duration.—The maximum was in forty-seven women 138 hours; the minimum ten hours, the mean sixty-three hours. Circumstances influencing the

force and duration of the souffle, are the contractions of the uterus, death of the foetus *in utero*, long previously, and profuse hæmorrhage. In two cases of puerperal fever, the sound was heard for two days in spite of the fever. The uterine contraction either enfeebles the sound, rendering it very short and very harsh, or completely arrests it; only once was it found to increase it. The delivery of a macerated child increases the tone; the same is observed *ante partum*. The explanation is, that the death of the foetus lessens the vitality, and as a consequence the tonicity, of the uterus, and increases the disparity of size between the extra-uterine arteries and their interstitial branches. Excessive hæmorrhage is believed to act in the same way.

Anatomical Seat and Approximate Case.—The observations made during the investigation of the *post partum* uterine souffle fully coincide with those of MM. Chauveau and Boudet, and conclusively prove that it has its seat in the arterial uterine system, and that its approximate cause is the passage of the blood from relatively smaller vessels into larger sinuses and vessels. M. Bailly comes to the following conclusions.

1. The expulsion of the child and the secundines does not at once arrest the uterine souffle of pregnancy, but nine out of ten times it exists a variable time after delivery.

2. Its tone is soft, without pulsation, and clearly intermittent. Any other character is very exceptional.

3. The intensity of the souffle gradually diminishes until it entirely disappears. As long as it lasts, it alternates between more or less elongated increase and diminution, of which the exact cause is not very apparent.

4. Its mean duration is between two and three days (sixty-three hours); in rare instances, it is prolonged to the sixth day.

5. The souffle can not have its seat in the vessels situated behind or at the sides of the pelvis, but evidently depends on modifications impressed on the vascular apparatus of the womb by pregnancy, which is conclusively proved by uterine contraction, either enfeebling or completely suppressing it.

PETIT ON MULTIPLE DISJUNCTIONS OF THE BONES OF THE FACE IN A FETUS.—M. Ch. H. Petit (*Le Progrès Médical*, p. 413) relates a case of a presentation with prolapse of an arm and the cord, thrombus of the vulva, and rupture of the uterus.

The medical man who attended the patient stated that the thrombus appeared before making any attempts at delivery. He applied the forceps, but entirely failed after repeated trials to deliver. When admitted into the hospital under M. Chantreuil, she was in a collapsed state; that gentleman replaced the arm, and recommended no further intervention but to stand by and watch until the head came down, which he thought would slowly take place; but should the head not rotate, then he would perform cephalotripsy. The arm again came down, the patient became more and more restless until the pains gradually died away, and she sank ten hours after her admission. M. Chantreuil declined to interfere, as it was useless. The necropsy showed a rupture of the uterus at the right side with the foetus half projecting through it into the abdomen. The foetus was beginning to decompose. The remarkable part was, that the bones of the face and portions of the several bones were completely disarticulated. The

lower jaw-bone was separated at the symphysis. The malar bones were disjoined from the zygomatic processes and from the superior maxillary bones; the latter were separated from each other, and the sutures between the nasal processes and the frontal bone were disjoined. The same was the case with the connections between the vomer and the palate and other bones. Where these separations had taken place the periosteum was torn off; but there was no infiltration or escape of blood in the vicinity of these joints, showing they were *post mortem*, and evidently caused by the force used in the attempts at extraction by the forceps. M. Chantreuil believes that, if the woman had been left to herself, and there had been no attempt at delivery, either by version or forceps, she would have done well. Interference had excited strong uterine contractions, which terminated in rupture of the uterus.

SKENE ON DERANGED MENSTRUATION.—In the *New York Medical Record* (September 1, 1874) Dr. Skene states that a sea-voyage will often produce amenorrhœa, as he believes, from shock to the nervous system. He is constantly in the habit of seeing strong, healthy young emigrant girls, who have always, previously to their voyage across the Atlantic, menstruated most regularly, affected with suppression of the menses; this is especially the case if the catamenial flow come on whilst at sea. In delicate females, care should be taken not to undertake a sea-voyage during the catamenia.

The author relates a very interesting case of amenorrhœa from defective development of the reproductive organs. The person was a lady, thirty-two years old, who died suddenly of apoplexy. The external organs were known to be present during life, but she never menstruated. She became masculine in appearance as she developed into the woman. The mammae were small, like a man's, a beard grew black and heavy, the forehead became bald, and she walked like a man.

The necropsy showed all the reproductive organs present, but rudimentary in form. The ovaries were small, and defective in Graafian follicles, which were entirely absent.

W. C. GRIGG, M.D.

MISCELLANY.

FEMALE SURGICAL PRACTICE.—The *New York Medical Record* of September 1, contains a report of a case of successful operation for recto-vaginal fistula performed on a lady, in which the operator was Dr. Susan Dimock, Resident Physician to the New England Hospital for Women and Children.

THE SOLVENT ACTION OF PAPYA JUICE.—In vol. lxi. (Jan. to June, 1874) of 'Braithwaite's Retrospect of Medicine,' will be found some account of the remarkable solvent action exercised by papya juice on the nitrogenous articles of diet. Dr. G. C. Roy, having found that in India cooks are accustomed to add a few drops of the milky juice of *Carica papya* to tough meat to make it tender, instituted a variety of experiments on the subject. He found, in fact, that the drug has a remarkable disintegrating power upon animal matter, without, however, promoting putrefaction. It may, not impossibly, be a nitrogenous ferment, standing in the same relation to albuminoid bodies as yeast does to starch. The plant does not appear to possess any poisonous properties, and the meat which had been the subject of the author's experiments was repeatedly eaten by a cat without injury.]

DR. G. J. ARKHANGELSKY has just published, in the Russian language, a book of importance to sanitary science, 'Cholera Epidemics in European Russia for fifty years, from 1823 to 1872.' The materials which the author has collected and tabulated did not exist before for the general European public, being stored in official bureaux in the provinces, whence the author had to disinter and arrange them.

ANIMALS AS MOTOR POWERS.—M. Marey has laid before the French Association for the Advancement of Science some interesting observations on the employment of animals as motor powers. He proves by means of a very elaborate instrument that the movement of animated beings as motor powers takes place by jerks, whence result shocks, and consequently a waste of labour. As an illustration of this theory, M. Marey cites the effort necessary to draw a burden behind one. If the necessary force be transmitted by means of a rigid or almost unextensible strap, for instance, of leather, the movement is jerky and more difficult than if it were transmitted by an elastic strap. It would therefore be better to attach horses to the shafts with India-rubber traces. He also gives as an illustration the manner in which boats are always dragged along the towing paths by long ropes. It would be impossible, or at least very distressing, to employ short ones. The length of the rope, which alternately tightens or slackens by slow oscillations, has in this case the same effect as India-rubber.

FEMALE SURGEONS'-ASSISTANTS.—The Russian Society for the Aid of the Sick and Wounded, having considered the insufficiency of the Russian Army Medical Service in time of war, have arrived at the conclusion that it is advisable to supplement the deficiency by the aid of female surgeons'-assistants. They therefore wrote to the university centres, commencing with the University of Dorpat, to ask their aid in organising the proposed body of female surgeons'-assistants. Encouraging replies have been received from Kazan, Simpheropol, Moscow, Kiev, Wilna, and Warsaw. The medical committee of Wilna University declare themselves to be thoroughly disposed to afford every facility for the instruction of female surgeons'-assistants. At the Military Hospital of that city, the house-surgeons have offered to devote some hours daily to the instruction of the women students, and the surgeon whose duty it is to teach the male assistants, has expressed his willingness to occupy himself daily, without any charge, with the theoretical education of the women. The consulting surgeons, on their part, will give up an hour of their time, or even more if required, to the same task.

NARCOTISING HORSES.—We learn from the *Gazette Médicale de Bordeaux* that an eminent veterinary surgeon has informed the Medical and Surgical Society of that city that the coachmen of certain families had been for some time in the habit of administering chloral to the horses in their charge, so as to make them easier to ride or drive. It appears that the drug acted like a charm, for horses which had previously been so spirited as to give much trouble to their drivers, became as quiet as lambs after a few days of this hyposthenic treatment. This great change naturally attracted the attention of the owners of the animals, and they sent for the veterinary surgeon to ascertain the cause of this sudden gentleness. That functionary noticed a certain tendency to sleep in the animals; but scarcely knew to what to refer this unusual condition, when in one of his visits he chanced to find a bottle half full of chloral. Here, then, was the *corpus delicti*, and when the veterinary surgeon questioned the delinquent coachman as to the use he made of the drug, the latter, after much hesitation, owned that, following the advice of a brother whip, he gave his horses a dose of chloral every morning to make them go quietly, and further, that many of the fraternity in Bordeaux followed the same plan.

THE SURGERY OF THE STONE AGE.—At the recent prehistoric congress at Stockholm, Dr. Prunières laid before his colleagues the results of a series of minute researches on the artificial perforations of the cranium and the cranial amulets of the neolithic period. The communication was accompanied by a numerous collection of crania, showing regular preparations of a circular form, varying from the size of half-crown to five-shilling pieces. A large quantity of circular pieces of bone were also found at the side of the skulls. All these perforations were made with flints; some on the living subject, the others *post mortem*. The first kind showed a process of cicatrisation, which generally indicated a duration of several years. In one case M. Broca judged from the condition of the bony plate which was attacked by osteitis, that the patient had succumbed less than a year after operation; but this was an unique instance. The perforations were situated on different points of the cranium, on the parietal and occipital bones, the forehead, etc., which seems to exclude the idea of a religious rite. They were performed on children as well as adults, and according to Dr. Prunières, this trephining seems to have been performed with a medical purpose, to give issue to a real or imaginary disease. The surgeons who operated with flint instruments scraped the bone layer by layer until they came to the dura-mater. On the dead body many circular pieces of bones were removed from persons who had already been trephined and cured. These pieces, instead of being scraped, have generally been sawn; and it is found that a certain number of concave pieces have been removed from the edges of the original trephining. Finally, it has been observed that fragments of bone have been replaced on the crania from which the small circlets have been removed, before interment; doubtless to allow the deceased to make his appearance in a complete state in the next world. MM. Prunières and Broca believe that they can see in this practice the most ancient material proof of belief in another world. M. Prunières is disposed to believe that trephining was only performed on the insane and on epileptics—the *friends of the gods*, according to old beliefs—and that the bony fragments removed were held sacred and used as amulets.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17s. 4d.; free by post, 19s. 6d.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & CO., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The First Volume, containing upwards of Two Thousand Articles abstracted and compiled by a staff of Fifty Hospital Surgeons and Physicians, is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for the year 1873 are also ready, price 1s. 6d. each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & CO.—Calcutta: THACKER, SPINK & CO.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & CO.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & CO., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S.W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, OCTOBER 28, 1874.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

ON THE TREATMENT BY MINERAL WATERS OF CHRONIC DISEASES, AND ON THE PRINCIPAL SOURCES ADAPTED TO THE VARIOUS MORBID CONDITIONS. BY M. GUBLER.*

(Continued from page 661.)

II. Treatment of Obesity and of Excessive Leanness.

Mineral waters have chiefly been used in the first of these conditions. The second of them has been less treated with them, no doubt because it was considered only a symptom of a morbid condition, which disappeared when that condition was removed; but the absence as well as the excess of adipose tissue constitutes sometimes an independent morbid condition, requiring special treatment.

The sedative action of a mild and humid atmosphere is favourable to the return of *embonpoint*. On this account, I recommend the climate of Pau and of the basin of the Adour. Prolonged tepid baths in indifferent waters, such as those of Neris, Bagnères de Bigorre, Ussat, Aix-en-Provence, are likely to produce good effects. One may equally use the eupeptic, blood-making or nourishing waters of primitive and volcanic lands—and perhaps the copper and mineral waters for their metamorphic powers. Who knows that the copper waters of Bagnères de Bigorre, of Balaruc, and of Saint-Christau, may not some day be the great restorers of rounded outlines to the spare forms of the fair sex?

For a long time foreign baths have had a monopoly of the treatment of fat and overgrown people. The cure by emaciation is tried at Driburg, at Ems, and Kissingen, and especially at Marienbad.

The alterative and purgative action of such waters is assisted by spare diet and violent exercise and sweating. Nothing should be easier than to produce similar effects in France, with some of the purgative waters—for instance, at Brides, at Neris, at Santenay, at Montmirail, or at Mont Dore, at Chatel Guyon, Saint-Maurice, and Saint-Nectaire. Many of these places are situated in an agreeable and picturesque country and have sufficient establishments.

[M. Gubler is not entirely *au fait*, when he talks of German waters. Surely the iron waters of Driburg are not attenuating. What he says about copper and arsenical waters is purely conjectural. Neris and Mont Dore have excellent establishments; Aix-en-Provence, Chatel Guyon, and Saint-Nectaire, milder ones.—*Trans.*]

III. Treatment of Lymphatism and of Scrofula.

I conform to usage in associating those two terms. Nevertheless, I by no means admit that scrofula is

the highest expression of the lymphatic temperament, for it may manifest itself in those who have none of the signs of the regular lymphatic temperament. Scrofula attacks all temperaments; but, as its most common lesions affect the different divisions of the lymphatic system, vessels, plexuses, and glands, we may be allowed to study them at the same time as the modifications of this system, which may act as predisposing causes. Dry and tonic climates suit the predominance of the lymphatic temperament, so also sea air and baths, and restorative and stimulating waters—also iron ones, and those of chloride of sodium, even sulphurous ones; in fact, all those complex waters which contain all the salts necessary for the serum and the blood-corpuscles.

France contains a long series of excellent sea-side places which have well arranged establishments, and have often a large concourse of visitors, along the shores of La Manche, the Atlantic, and the Mediterranean. They are so well distributed, that we may have sea-baths the whole year through. Some foreigners bathe all through the winter at Cannes, Nice, and Mentone; and I only wish their example was followed by more patients.

Sandy shores and dunes of sand, in which they may take dry and hot baths, suit particularly well strumous patients. Arenation, along with sea-air, modifies profoundly the lymphatic and scrofulous constitution. It is always an useful supplement to sea-bathing. For very young children one selects creeks, where the water is shallow, and the waves are weak.

The combination of these favourable circumstances may be found in a great number of stations, from which one must select the nearest one, that has a favourable climate for the particular season. In summer, the coasts of La Manche or Bretagne; in spring and autumn, those of Arcachon and the Gulf of Gascony; in winter the baths of Montpellier, Cette, La Ciotat, Cannes, Nice, etc.

Such are the general indications for the treatment of the scrofulous; but there are also some special ones with reference to the varied manifestations of the diathesis.

Scrofula produces cutaneous, glandular, osseous, and visceral lesions, all of which have to be taken into consideration; but in my opinion the most important point in practice is, whether these lesions are so situated that the mineral waters can be actually applied to them. An osseous lesion may be so situated, as to make such treatment possible of application at one time and not at another.

External scrofulous lesions, enlargements of glands, periostitis, and superficial inflammation of bone are exactly suited for sea-baths or strong salt-springs, whose action is the more powerful in proportion to the solution of continuity that may be present. Subjects suffering from cutaneous ulcerations, from sinuses and fistulæ, the result of the supuration of glands or of bone, are the cases that profit most by a course of salt waters. But, as in such cases the action is nearly proportionate to the strength of the water, the stronger ones are to be preferred. On this account, Salies de Bearn, because it contains 260 grammes and more of salt in the litre, is to be preferred to all waters, foreign or French. Far behind it come Salies (Haute Garonne), Salins (Jura), Salins Moutiers (Savoy), then Uriage, Balaruc, and Bourbonne, Lamotte, etc. The topical action of salt waters is increased, by strengthening them with the addition of the mother or concentrated liquid.

* *Journal de Thérapeutique*, no. 10 et seq.

However, the density of the saline solution is often not the sole point of importance—its warm temperature may be equally important. Salins (Savoy) possesses the quality of warmth along with a mineralisation superior to that of Kreuznach, whose not very powerful water by no means deserves the great reputation it has, even amongst us. The piscinas of Moutiers, fed by a powerful thermal water that is always running through, are particularly well suited for young children, who may swim in them; while the richer springs of Salies are better suited for older subjects, who are less active, or are perhaps not able to move owing to strumous affections, or old ulcers, and fistulous passages, which cannot be healed without very strong local stimulation.

Deep-seated scrofulous lesions require the internal use of waters capable of altering the nutrition. Here the strong salt-springs fail us, for we can only drink them in very small quantity without causing irritation and diarrhoea. Waters not so strong, especially if they contain carbonic acid, are to be used. Such are those of Saint-Nectaire, and similar ones in Auvergne, which one can drink in glassfuls, which is impossible with the strong water of Salies, or even the weaker one of Salins (Jura). The water of Salins Moutiers is to be preferred, because it is slightly gaseous; also on account of its warmth, which aids its absorption by the stomach. These two favourable conditions are fulfilled in one of the springs of Nauheim, a bath the richest in salt-wells in Europe. Warmth of waters is also useful, in stimulating by its baths torpid constitutions, and no doubt the success of sulphur-baths is mainly to be attributed to the activity which heat imparts to the cutaneous functions. Nevertheless, Aix, Barèges, Luchon, and the crowd of other Pyrenean stations owe something to the alterative action of their mineral constituents.

The waters of Uriage, unfortunately only tepid, have the advantage of having a little sulphur associated with a large proportion of neutral salts and chloride of sodium. But those of Gréoulx, which possess a high temperature, appear to me to be suited for all the requirements of hot hydrotherapy, and by their very complex constitution seem called to do great service to scrofula, especially in its torpid forms.

Glandular, osseous, and visceral scrofula, in which inflammation, or a general condition of erethism is present, especially if there be any ulceration, will do best with sea-water, or Salies de Bearn, Salins de Jura, or Salins de Savoy; or, in the absence of erethism, will do well with the waters of central France, or in some complex cases with Bourboule, owing to its arsenical water.

[It is by some slip that M. Gubler talks of the sea-baths of Montpellier. His wish to bring forward Salies de Bearn is very natural, but for the present France is far behind Germany in salt-springs of all kinds, especially in the knowledge of how to use them. Salies is not stronger than Halle in Austria, strong though it is. Uriage and many of the baths mentioned are pleasant places. Royat is a more comfortable place than Saint-Nectaire: its waters are similar, but less powerful. Both of them deserve the notice of the English.—*Trans.*]

IV. *Treatment of Tuberculosis.*

In chronological order, tuberculosis comes next after scrofula. These two affections, manifestations of the same diathesis, are often identical in form, while they may differ in seat. The same treatment

is applicable to both, with some modifications, having regard to the seat of the lesions, the importance of the organs implicated, and the degree of constitutional disturbance. The tubercular diathesis prefers less powerful waters, and requires less active balneological proceedings, and, indeed, sometimes an extreme reserve in the employment of external measures, and prudence in the internal use of waters.

Medicine cannot, of course, do anything for the tubercular diathesis, but it may modify many disturbances of the circulatory nervous or nutrient systems arising out of it. Firstly, supposing tuberculosis to be suspected rather than proved to exist, that the symptoms are undefined, that no febrile disturbance has manifested itself, that only the digestion is impaired, the strength is falling off, and the nutrition failing; in such a case one orders carbonated saline and even iron waters, especially those of Royat. Many other waters of the same class in the centre of France would render the same services, but their establishments, where there are any, are deficient in comfort. I count the water of Royat to be real mineral lymph; but there are others more powerful, especially in containing more iron, which have been already cited in the treatment of anæmia, which, in the absence of any febrile excitement, are still better for bracing the drooping constitution.

In the second place, if the pulmonary affection be well marked, and its course rapid, and attended with fever, there is no use in thinking of any mineral water-cure.

If, after having been galloping, the disease abate its pace, still preserving a tendency to inflammation from time to time, or if in the course of torpid tuberculosis acute symptoms, such as secondary pneumonia or pulmonary hæmorrhage, occur, in such cases one must wait for the remissions, and then prescribe only some waters destitute of any irritating property. The type of these inoffensive and soothing waters is to be found in the thermal sources of Mont Dore, with their minute quantity of chloride of sodium and carbonate of soda, and even of arsenic. Only the routine cure of the place must not be followed. Violently hot baths and inhalations of heated vapours must give way to milder modes of treatment, more in harmony with the feeble constitution of tubercular patients. I begged in 1872 that the drinking should be made more important, and the bathing less violent, and I think that some change has taken place; Royat, whose water is more mineralised, is, like Mont Dore, suited for tuberculosis with erethism, and has now for some years received many such patients. These two stations, which are analogous to Chateaufort, Rouzat, Saint-Myon, and Saint-Maurice, occupy the same place in France, as Ems does in Germany, and they are superior to it in elevation and consequent sanitary conditions. Bourboule, remarkable for its complex saline waters, and for the unusual quantity of arsenic which they contain, ought to operate in these cases like Mont Dore and Royat. But I believe that the Bourboule waters are especially efficacious like the different springs just mentioned, and Saint-Nectaire, in lymphatic and strumous subjects with torpid phthisis and circumscribed caseous deposits. They contain a greater variety of salts, and they can do more for the patient than the chloride of sodium waters of Soden, which have obtained a certain vogue in Germany in phthisis.

Thirdly, if the symptoms of tubercular affection be undoubted, but the pulmonary lesions proceed

slowly, without causing much reaction, for this form, which is usually accompanied with more or less bronchial catarrh, the sulphur-waters usually recommended are suitable.

Nevertheless, the waters containing sulphide of soda or of lime are not absolutely excluded in the case of subjects who have had spitting of blood, and who have evening febrile exacerbations. It is only necessary to guard against their stimulant effects. No doubt a hæmoptysis, if not spontaneous, has nothing very formidable in it, but it should be avoided if possible. In this we shall almost always succeed, by giving small doses of the water to drink, and by not employing baths; sparing the patient the great heat of the baths, and of the inhalation rooms. If, in spite of these precautions, hæmorrhage take place, it is probably owing to other circumstances than the use of the water. Bordeu justly called these waters the mildest of all pectorals. I think that it is on their alterative effects that we have chiefly to count. But their intimate operation on the parenchyma will take place most satisfactorily when the water is administered so gently that it can excite no revolt of the system.

But whatever may be the physiological operation, by which sulphur-waters ameliorate the condition of tuberculous sufferers, the fact that they do so is incontestable, and every day experience confirms that of centuries. Generally speaking, the warm soda sulphur-waters are superior to the cold lime sulphur-ones. Almost any of the Pyrenean waters might be utilised for pulmonary complaints. But, on the whole, the more fixed waters with a sufficient amount of mineralisation, and of a temperature that will allow them to be drunk as they issue from the source, are the ones to be preferred. Thus the more alkaline waters of the Eastern Pyrenees are somewhat more sedative, and are more suitable than those of the central chain, when there is a tendency to vascular erethism. Among such stations, Vernet and Amélie are suited for winter cures, and next, the feebler sources of Luchon, Cauterets, and especially Eaux-Bonnes. The La Raillère spring at Cauterets enjoys much repute in chronic affections of the pharynx and larynx; but these, as well as bronchial and other pulmonary affections, derive just as much benefit from Eaux-Bonnes, which is more crowded than ever with patients of this class. The waters of Eaux-Bonnes are distinguished from others, in containing small amounts both of chloride of sodium and of sulphide of calcium, forming thus a sort of transition between the waters, which contain these two kinds of salts separately.

Among the calcium sulphur-waters many stations deserve their high reputation in tuberculosis, as Enghien, Pierrefonds, Cambo, Guagno, Challes, Marlioz, Allevard, Saint-Honoré, and others, in France, and Schinznach, in Switzerland. Most of these places are provided with good establishments, and the arrangements for pulverising the water and the inhaling rooms appear to me to be particularly good at Allevard, Marlioz, and Saint-Honoré. Thus, by the aid of art, the lime sulphur-waters prove themselves useful in cases of tuberculosis requiring soothing. The topical application of the sulphuretted hydrogen acts as a sedative, while the portion of it which enters by the stomach exercises its alterative action on the circulation. Challes is the strongest of all the sulphur-waters, and contains also a certain amount of iodine.

But Gréoulx is distinguished from all other

stations by the happy association of sulphur and of iodine with a considerable dose of chloride of sodium; this, joined to the abundance of its waters, and their high temperature, and the southern climate of the place, assures it a high place for the future. To sum up, if a phthisical patient come to me for directions as to a mineral water, my first thought is to send him to thermal soda sulphur-waters, Bonnes and Cauterets in summer, Amélie or Vernet in winter.

It is only where there is much erethism, or a recent hæmoptysis, that we have to think of some sedative waters. Then it will usually be sufficient to let the storm blow over, and send the patients to some of the less exciting waters, recommending inhalations at Enghien, Pierrefonds, Saint-Honoré, Marlioz, or Allevard.

But if the case be very pressing, the patient should be sent to Royat, Mont Dore, or Chateaufort. If there be scrofula with erethism, Bourboule is to be advised. On the contrary, if the form of the disease be scrofulous with torpor, Gréoulx is to be preferred.

In fine, if there be merely threatening of tuberculosis, based on anæmia or lymphatism, some of the restoring and alterative waters, such as La Bourboule, Royat, and Saint-Nectaire, will be found to be of most service.

V. Chronic Inflammation of the Respiratory Organs, Asthma, and Pulmonary Emphysema.

The waters useful in tubercular cases are equally so in these affections. In general, chronic laryngitis with or without granulations, chronic bronchitis, with mucous or muco-purulent expectoration, require sulphur-waters, soda or calcium ones. They are not to be employed in the acute stages. But in the transition between the acute and chronic, the only waters which are innocent, and at the same time efficacious, are those which combine more or less alkali with chloride of sodium. The lighter waters of Vals and those of Soultz are often useful. The source Puits Chomel at Vichy formerly had some name in such cases, and I have often seen the effects of thoracic inflammation removed by Royat, Mont Dore, and analogous waters.

But if the affection be chronic, and there be no inflammatory action, then the indication is absolute. The sulphur-waters of Bonnes, Cauterets, Amélie, Le Vernet, Luchon, Aix, or Enghien, Pierrefonds, Saint-Honoré, Allevard, Gréoulx, or of Schinznach, are to be ordered.

With a tendency to lymphatism or obesity, and especially if there be any tendency to cutaneous affection, we may advise Uriage, Saint-Gervais, and sometimes the at once purgative and sulphur waters of Vaqueyras-Montmirail. If the bronchial catarrh be inconsiderable, if the chief indication be derived from pulmonary emphysema, and the nervous condition which constitutes the asthmatic state, then Mont Dore is usually to be preferred, especially in patients of a gouty, arthritic, or dyspeptic tendency.

We should, on the contrary, have recourse to the sulphur-waters if the pulmonary disturbance be dependent on a strumous habit.

[Here, again, Gubler purposely overlooks the German waters. He only mentions Ems and Soden. Germany has, unfortunately, no mineral waters for tubercular patients that enjoy as good a climate as the South of France; nor, with perhaps some exception in favour of Silesia, has it any elevated spots,

like Mont Dore or the Pyrenees. Still Weilbach, Lippspringe, Neuenahr, Bilin, and some other waters should have been mentioned. Many of the places mentioned by M. Gubler have comfortable establishments. That at Challes is quite new; its waters are undoubtedly remarkable ones, but their effects are but partially known. I can speak of most of these French places from personal inspection. I found Amélie-les-Bains quite comfortable in winter, but not a very cheerful place. M. Gubler seems to have unbounded faith in his waters. The question always remains, how far it is a southern climate, and mountain air, and the simple moist air of the inhaling rooms, that do good, or the infinitesimal doses of sulphuretted hydrogen, or of chloride of sodium, or of salts of calcium. But the main question is, do patients benefit as much as M. Gubler represents? I observe, that in certain cases of premonitory symptoms of phthisis, M. Gubler orders iron waters. They were in former days the ones most in use in such cases.—*Tr.*]

J. MACPHERSON, M.D.

(To be continued.)

CHARPENTIER ON HÆMORRHAGE FROM PLACENTA PRÆVIA.

Dr. Charpentier, in lectures published in the *Archives de Tocologie* for June, July, and September, treats of placenta prævia: its mechanism, progress, diagnosis, pathological anatomy, and treatment.

Mechanism.—The author gives a brief review of the various theories that have been propounded to explain the cause of the loss of blood, from the earliest date to the present time. Portal and Giffard believed it to arise from the opening up of the cervix, and a consequent laceration of the veins which, from the insertion of the placenta, were in contact with this organ. It was only from M. Levret's time that a rational and true theory of this accident began. The neck of the uterus, said this author, becomes the point of insertion of the placenta, and during the last months of gestation takes part in the development of the uterine cavity; the placenta is stretched and detached; hence the hæmorrhage, the moment the labour begins, consequent on the opening up and dilatation of the cervix. The more completely the placenta covers the os, the greater is the loss of blood. This theory was universally adopted by the English and German accoucheurs, as well as by the French; but it did not satisfactorily explain all the cases of hæmorrhage during the latter months of gestation and before labour set in. M. Stolz demonstrated, contrary to the then received theory, that the cervix did not participate in the changes in the uterus until within the last few weeks of pregnancy; often, indeed, not until the last days. M. Jacquemier first propounded the theory now universally accepted, viz., that when the insertion takes place at the fundus or upper part of the uterus, the ovum finds itself at first in a very large cavity, relatively to its size, and, increasing proportionately with the development of the womb, it only begins to be mechanically pressed at a somewhat advanced stage of pregnancy; but from that time the development of the fundus and of the superior portion of the uterus is less rapid, because the inferior portion commences to yield, in its turn, to the enlargement of the organ; and the detachment of the placenta is only possible in case of extreme distension of the uterus. But this is no

longer the case when the placenta is fixed on the internal os, or a short distance from it. The cavity of this part of the uterus forms a narrow canal; the placenta, very large from the first, partly covers it. The development of this narrow cavity proceeds from below upwards; and, as it is small in comparison with the ovum, its increase is premature; and it is more rapidly expanded than when the reverse is the case. During the first half of gestation, the placenta is prevented from being put on the stretch, partly by an increase which at first is very rapid; but later it is subjected to a distension which at an early period may lead to its partial separation. Hence the hæmorrhage during the fourth, fifth, and sixth months. When to the organic augmentation of the placenta becomes added the mechanical distention that acts on the lower segment of the uterus, and which makes it protrude more or less into the cavity of the pelvis, the dragging increases in a very marked manner, and often leads to a separation of a portion of the placenta. Hence the frequent increase of hæmorrhage during the seventh, eighth, and part of the ninth month, because the os should be firmly closed until the commencement of labour. When labour has set in, Levret's explanation fits exactly. It is the dilatation of the os that at this period is the real cause. This theory has been accepted by all accoucheurs up to the present time, with the exception of Dr. Barnes, and Sir James Simpson, who, however, are diametrically opposed to each other. Dr. Barnes assents to the theory of the detachment of the placenta, and that the blood comes from the uterus; whereas Sir J. Simpson maintains that the hæmorrhage comes chiefly from the placenta. If Jacquemier's and Levret's theory were correct, fatal hæmorrhage ought to occur at the time of labour, when the cervix dilated; but this is not always the case. In cases where there is only partial placenta prævia, it is easily explained; for when a portion of the placenta, contiguous to the os or covering it, has been detached, and the bleeding has ceased, the tendency to new partial detachments may disappear, because the progress of augmentation for the lower portion of the uterus removes very perceptibly the margin of the placenta most exposed to these new detachments, from the centre of the inferior segment, which is the part most mechanically distended; and again, because the dragging of the inferior border of the placenta on the superior portion is much diminished, being situated high up in the cavity of the uterus. But when it is a complete placenta prævia, the hæmorrhage should be inevitable; nevertheless, although during gestation it may have frequently occurred, it does not in some cases happen during labour, although the placenta continues to cover the orifice, and is pushed before the advancing head. Walter asserted that, in spite of the detachment of the placenta, the communications between the venous radicles and the arterioles were sufficiently large to permit the return of the blood into the veins without its escaping. Mercier asserted that, under the influence of a perversion of sensibility, the circulation was arrested. These theories are obviously erroneous. Moreau thought that death of the fœtus led to arrest of the circulation; but, even when the fœtus is dead, a detachment of the placenta is always accompanied with hæmorrhage. Jacquemier believed that in these cases the placenta was completely separated, or, at least, as far as the internal os, so that dilatation could proceed without

detaching any more, and that the utero-placental vessels were closed by coagula. Simpson, taking up the old idea of Rawlins of Oxford, declared that if the exposed uterine vessels contributed to the hæmorrhage it was very slight; that the blood came principally from the placental vessels. If this were true, removal of the placenta would cause the bleeding to cease, which, in many instances, is not the case. Dr. Barnes, adopting the ideas of Stolz of the integrity of the cervix, allows that the first hæmorrhage comes from excess of development of the placenta upon the cervix, a part not suited for its insertion. When the catamenial periods occur, the blood flows to the uterus and placenta, rendering the latter too large for the surface to which it is attached; it becomes separated at the margin of the internal os, and hæmorrhage takes place. Then, under the influence of the irritation caused by the partial detachment, and of the infiltration of blood into the substance of the placenta, and of small clots between the placenta and the uterine walls, the uterus is excited to contract. The contraction of the cervical zone may separate a larger portion of the placenta, but the detachment will never proceed beyond this zone. The true cause of cessation of the bleeding is energetic contraction of the uterus. No matter how produced, the hæmorrhage does not stop because the placenta is removed, but because the uterus is made to contract. The uterus is divided into three zones, the polar superior, meridian, and polar inferior or cervical zones. No accidents occur when the placenta is attached to the superior; when to the meridian, a tedious labour leads to *post partum* hæmorrhage. This theory of Dr. Barnes does not entirely belong to him. In 1865 Legroux published in the *Archives de Médecine*, a very interesting memoir, in which this idea may be found fully explained.

Progress.—Nägele was of opinion that, when it was complete placenta prævia, the hæmorrhage commenced earlier than when partial. Facts have justified this assertion. It is not rare, in partial placenta prævia, to have no bleeding until labour begins. According to Duval, there must always be some general cause; as, for instance, the menstrual molimen. The hæmorrhage is never internal; perhaps in some few instances a clot may close the orifice and so act as a plug to arrest the hæmorrhage momentarily. Labour is frequently in consequence premature. M. Gendrin's statement that labour does not begin in these cases until the foetus is dead, is contrary to facts. When labour sets in, the hæmorrhage is arrested of itself without any intervention, only in the following circumstances. 1. If the woman be not too much exhausted, if the os be soft, dilatable, the pelvis well formed, the presentation favourable; and if, above all, the uterine contractions be energetic. 2. If the insertion be marginal, and the waters break, then the head descends and acts as a plug. 3. If the placenta be torn through at its centre, allowing the escape of the liquor amnii and the foetus. This is a very rare accident. Portal, Wilks, Ingleby, and Jacquemier, each report a case. 4. If the placenta be expelled in advance of the foetus. Simpson founded his treatment on this. The hæmorrhage does not always cease with expulsion of the child, and frequently women succumb afterwards to inertia of the uterus.

Diagnosis.—The hæmorrhage rarely begins before the sixth month, generally at the seventh or eighth of pregnancy. Any loss of blood beginning at these

epochs is very suspicious of placenta prævia. If to this be added the absence of *ballotement* it becomes almost a certainty. This arises from the placenta, by its attachment to the lower segment of the uterus, distending and raising it up high in the pelvis, and also increasing the distance between the foetus and exploring digit, so that consequently the finger is prevented from feeling the impulse. Again, the presentation is frequently abnormal, which increases the difficulty, as it prevents the foetus from being felt. Auscultation, as proved by M. Depaul, does not assist in ascertaining the placental site. When labour has once begun, there is no difficulty in the diagnosis. Whenever there is a suspicion of placenta prævia, vaginal examination should be conducted with the greatest care, as frequently hæmorrhage is induced. That the bleeding ceases during the pains in accidental hæmorrhage, but not so in placenta prævia, is not based on fact, and cannot be used as a means of differential diagnosis. Legroux showed that this was an error in the interpretation of observation, and propounded the following deductions, which are the same as those of Dr. Barnes. 1. No matter where the insertion of the placenta may be, all hæmorrhage is due to the detachment of the placenta, and it takes place during the diastole and repose of the uterus. 2. The contraction of the uterus arrests it. 3. The blood that escapes at the systole is accumulated during the diastole between the separated surfaces and in the vagina. 4. The hæmorrhage would be arrested if the contraction were permanent, or if the dissevered surfaces were so placed that they could not be separated during the diastole. 5. The bleeding is almost entirely uterine. The placenta contributes but little, which could only effect the foetus, not the mother. It becomes exclusively uterine when the death of the child intercepts the utero-foetal circulation. [The accusation made by Dr. Charpentier, and repeated more than once, that Dr. Barnes derived his theory from M. Legroux, and then claimed to be the originator, is contradicted by his own statement. 'Barnes ne connaissait qu'imparfaitement le travail de Legroux, car il l'attribue à Leroux.' . . . Before the author made such an accusation, he should have taken pains to substantiate it.—*Rep.*]

Prognosis.—This is always grave, both for parent and for child. Should the mother come through the labour safely, there is always a danger of her sinking afterwards from some future complication. Respecting the prognosis of the child, Leroux admits a loss of 1 in 3; Madame Boivin of 3 in 11; Madame Lachapelle, 13 in 23; Dr. Barnes, 29 in 62. Simpson collected 113 cases, with a mortality of 73. Out of 61 cases in the Clinique during nineteen years, 39 infants died. At the Maternité, out of 79 cases, 45 were born living. Respecting the mother, Simpson collected 654 instances, with a mortality of 1 in 3.6. Rigby gives a death-rate of 1 in 3.8; Bland, of 1 in 3. At the Clinique 36 died and 19 were saved, the result in 8 is not stated. Barnes lost 6 out of 62. The Maternité report gives 70 mothers saved out of 79 cases; but the latter statistics are not reliable, as the records have been very imperfectly kept.

Pathological Anatomy.—The uterus, but above all the placenta, in these cases, presents various peculiarities. The placental site is the most vascular part of the uterus. Should the placenta be attached on the lower segment, or upon the cervix, these two parts become very vascular; the superior segment is

more spongy, thicker, and permeated with wide uterine sinuses, which account for the great hæmorrhage and the rapidity with which the patient is prostrated. The placenta and membranes invariably present such marked features, that placental presentation can be easily recognised after they have been extruded or expelled; and in some cases, by the sense of touch during labour, when it is partial, and the protruding membranes can be felt, they are found, instead of being thin and soft, thicker and more roughened. If the placenta have been in the normal position, and, on its expulsion with the membranes, the opening into the bag be found in the centre, as in natural labour, the membranes rupture at the most pendent point; but in complete and partial placenta prævia the rupture is situated close to the margin. In some instances, the membranes are completely separated from the placenta. Sirelius, of Helsingfors, published a memoir in the *Archives Générales de Médecine*, of 1861, wherein these various alterations are studied. Sirelius maintains that the villi grow from the decidua and not the chorion, and that they are bathed with a nutritive juice proceeding from a well-formed decidua. If the ovum be developed at the fundus of the uterus, these multiply and ramify; if, on the contrary, the nutritive elements be less abundant, they multiply and ramify less, as, for instance, in extra-uterine gestation. Hence the question arises, whether the structure of the decidua is the same when the placenta is normally as when it is abnormally placed; and again, whether the decidua is closed, or one with a small opening opposite the os. Sirelius, Virchow, and Küssmaul believe that the decidua is not a closed bag, but that it has a small orifice closed by a button of mucus. The placenta, in connection with an incompletely developed decidua, and less vascular, undergoes corresponding modifications. Its form is more irregular; instead of being round, its appearance is fragmentary, the cotyledons are more separated from each other, and not so thick; in some cases it becomes nearly a membranous placenta; finally, in consequence of successive hæmorrhages, the external surface presents projections and beds of coagulated fibrine, and under the microscope specific alterations have been discovered. These observations are based upon six cases, three by Braun, one each by Gurlt, Barnes, and McClintock. Braun's cases had a secondary placenta (*placenta succenturiata*). These alterations consisted of a spreading out of the placenta into membranes, or its division into two by a groove; and, as a corresponding alteration, the interuterine-placental membrane was imperfectly developed opposite the orifices of the uterus, sometimes replaced by a thin layer of connective tissue, or by the decidua in the process of fatty degeneration, and scattered with pigment-covering and the lamina of placental tissue, where the villi were transformed into cellular tissue, forming flattened cotyledons next the uterus without the circular vein. If it be partial placenta prævia, the part in contact with the os alone exhibits these remarkable lesions, but only masses of fibrine and infarcts in the superficial layers on the interior of the villi. According to Lumpe, Seyfert, and Braun, when in placenta prævia the cotyledons are unequal in number, the chief portion of the placenta is attached to the right side in thirty-two out of thirty-nine cases. W. C. GRIGG, M.D.

(To be continued.)

ANATOMY AND PHYSIOLOGY.

TOUSSAINT ON THE MECHANISM OF REJECTION IN RUMINATION.—M. Toussaint, in a note to the French Academy of Sciences, says that hitherto the manner of the return of food from rumen to mouth, in rumination, has been in some obscurity. The phenomena of rejection are so complex and rapid, that it is hardly possible to determine them by simple observation; the mechanism can only be demonstrated with the aid of registering apparatus.

In studying rumination, physiologists have nearly always given their attention to the digestive organs, and the muscular forces acting directly on these, as the diaphragm and abdominal muscles; and little effort has been made to ascertain whether the mass of food is not only pushed into the œsophagus by such compression of the rumen, but also sucked into it by a particular action of the breathing organs.

M. Chauveau, however, has long affirmed this suction. According to him, the process is this. At the moment of rejection the glottis closes; then there is a very strong and sudden contraction of the diaphragm, producing considerable rarefaction of the air in the lung. This diminution of pressure is indicated by the strong flow of blood in the jugulars. It must have the same action on the matters in the rumen and the reticulum near the cardiac orifice, which are much dilated; they are urged, therefore, into the open orifice of the œsophagus. Then, immediately, a contraction of the right pillar of the diaphragm, cutting off these matters, provokes the antiperistaltic contraction of the œsophagus, which thus brings them into the mouth.

This theory, deduced from pure observation, has in all points been confirmed, M. Toussaint says, by experiments made in the laboratory of the École de Lyon, on the cow and the sheep. (The mechanism in both is the same.) A healthy cow being selected, a tube about two millimètres (about 0.08 inch) in diameter was introduced into the trachea, and connected with the drum of a registering apparatus. The thorax and the abdomen were then surrounded with Marey's pneographic belts, which transmit the movements of these parts. The animal was not excited, and began to ruminate immediately. A tracing was obtained which showed the relations between the intrathoracic pressure and the movements of the ribs and the abdomen.

In the respiratory movements, the three curves exactly superposed present similar undulations. When a movement of rejection occurs, the tracheal curve shows a preliminary elevation more or less marked, forming a plateau, and then going down considerably. The manometric measurements show that this fall corresponds to a diminution of pressure of about two centimètres of mercury. The ascent is not less rapid than the descent; the two movements take place in a half or three-quarters of a second; the curve rises again to its previous point, and remains there, describing a second plateau, during one or two seconds.

On examining the curves of the ribs and of the abdomen, it is easy to explain the peculiarities of the tracheal tracing. In the abdominal curve there is a sudden descent, which lasts the same time as the descent of the tracheal curve and corresponds exactly to it, in its two times. The descent can only be produced by a diaphragmatic contraction, which forces back the abdominal organs, and the ascent by

a relaxation of the diaphragm, aided by abdominal contraction.

The tracing of the ribs, on the other hand, shows an elevation of the curve at the moment of the diaphragmatic contraction, in consequence of a sinking of the thorax; the sinking is evidently caused by atmospheric pressure, which only ceases at the moment when the diaphragm is relaxed; so that the two tracings, similar during respiration, are at this moment in antagonism, and furnish opposite curves.

It is at the moment of contraction of the diaphragm that the alimentary matters are engaged in the œsophagus; for this tube has been caused strongly to dilate under the influence of rarefaction of air in the thorax and the elasticity of the lung. It is equally stretched through the backward movement of the diaphragm, which draws it with it. The dilute matters of the rumen are then precipitated into this orifice, as they would rise into a rigid tube when suction is applied.

To demonstrate the occlusion of the glottis, the arrangement being as in the preceding experiment, another fine tube is introduced into the superior meatus of the nasal cavities. During the respiratory movements, the curves of the nose and the trachea resemble each other completely; but immediately the glottis closes, the feather of the nasal apparatus becomes motionless in the zero position, and its trace is a straight line, which is exactly superposed on the great depression of the tracheal tracing, and the two plateaus which limit it before and behind.

It was interesting to know what would occur if the intrapulmonary air were not, at the moment of rejection, completely imprisoned, as is normally the case through closure of the glottis. Tracheotomy was therefore performed, and by means of a special apparatus, the trachea could be closed or opened at will, without interrupting the circulation of the air and without the animal being affected. Under such conditions, if the trachea be opened, a diminution of amplitude in the undulations of the pulmonary curve is observed. The plateaus which precede and follow rejection are no longer formed in the tracheal curve. The movements of the ribs and the diaphragm are now synergic, and that in the first movement, without there having been preparation of the animal. There was a very rapid inspiration produced by a sudden and simultaneous contraction of the ribs and the diaphragm, causing a diminution of pressure sufficient for the matters to be able to penetrate into the œsophageal infundibulum.

It is, then, pretty evident that the rarefaction of the air in the chest concurs largely in causing the passage of substances from the rumen into the œsophagus; but is this the only cause, and have not the contractions of the rumen and the reticulum their importance? To ascertain this, through a wound made in the œsophagus at the base of the neck, a probe was introduced as far as the anterior part of the rumen. The cow ruminated some hours afterwards with very great difficulty; and yet, in spite of the violent efforts she made to bring the substances into her mouth, during these efforts the capsule belonging to the rumen was never seen to displace the corresponding feather. The diaphragmatic contractions, on the other hand, were very pronounced. In this experiment, the ordinary movements of the rumen are nevertheless very marked; but they never correspond to movements of rejection, further, they are slow, and last at least eight to twelve

seconds. It appears, then, that in rejection, the rumen is passive.

Most authors, after inspection of the exterior movements of an animal in rumination, speak of a rapid inspiration and a no less rapid expiration. The movements of the abdomen and the ribs may indeed give this change; but the fact of the occlusion of the glottis shows us that there can only be change of intrathoracic pressure appropriate to a determinate end, but not true respiratory movements.

M. Toussaint also measured the velocity of ascent of the ruminated mass; its course is extremely rapid. It takes only half a second to a second to traverse the whole length of the œsophagus; and as the occlusion of the glottis lasts about four or even five seconds, the mass always reaches the mouth before communication is established between the lung and the air without. The first deglutition of liquid which follows the arrival of the mass in the mouth, takes place generally towards the end of the closure of the glottis.

When the animal swallows, there is occlusion of the glottis; the tracing of the nasal cavity returns, in that case, to the zero pressure. Before this occlusion, there is a movement of the belts of the thorax and the abdomen, which may be interpreted in the sense of a very light inspiration, if the deglutition occur during normal expiration, and a light expiration if it occurs during inspiration.

M. Toussaint concludes that the rarefaction of air in the lung is the chief cause of passage of alimentary matter from the rumen and the reticulum into the œsophagus; and that, consequently, there is not, properly speaking, a previous formation of bolus. This rarefaction is produced by a diaphragmatic contraction, while the glottis is closed. The ribs do not intervene.

The diminution of intrapulmonary pressure is indispensable to the penetration of the food into the œsophagus; for if an aperture is made in the trachea, the ribs then come to the help of the diaphragm, and rise suddenly and at the same time with it, to produce the depression instantaneously.

Deglutition is a phenomenon much more complex than has been supposed, and requires the concurrence of the diaphragm and the ribs.

HECKEL ON THE LOCALISATION OF MINERAL MATTERS IN SOME ANIMAL ORGANISMS. — In two recent communications to the French Academy (*Comptes Rendus*, August 24 and September 7), M. Heckel has made known some facts which throw light on the connection between localisation or accumulation of mineral or organic substances and the great physiological functions.

Insects are capable of absorbing arsenical matters, and resisting their hurtful action, if these be given in small doses, frequently repeated. M. Heckel experimented with *Mantis religiosa*, *Blatta occidentalis*, and *Cerambyx heros*; subjecting them, with great care, to a mixed arsenical diet (flour and metallic arsenic), during forty days. They were then killed, and the alimentary canal was dissected. Arsenic was sought both in the stomachal cæcums and the Malpighian tubes, but only the latter contained it very manifestly. There was nothing abnormal in the superior cæca. In the hepatic tubes, the cells of large dimensions which cover the tunica propria, contained a considerable quantity of fatty globules, while the granular matter was very much reduced. These elements are not alone modified by the metallic localisation; the physiological functions are dis-

turbed, for the liquid secreted by these organs loses its normal coloration, becoming quite colourless; its bitter taste also disappears. Judging by exterior characters, this Malpighian liquid might then rank among the products of glands exclusively urinary.

These phenomena M. Heckel regards as lending support to the view which looks upon the tubes of Malpighi as mixed organs (urinary and hepatic). This property of accumulating arsenic is almost characteristic of hepatic tissue everywhere in nature. In a voracious land-crab of the Antilles (*Gecarcinus ruricola*), after a similar experimentation of some days, the author always found arsenic manifestly in the hepatic tissue; and of the whole system, this was the viscus which contained most of it after prolonged experimentation. 'Here doubt is not possible; we have to do with a liver, and the similarity of action between the Malpighian bodies and this gland of determinate nature leads us to conclude an identity of functions. From the comparative anatomy point of view, the same connection has been happily pointed out by M. Milne-Edwards, who establishes the transition between the Malpighian tubes and the liver of Crustacea, by the tubes of Isopoda.'

M. Heckel extended his researches to Mollusca, experimenting on *Helix aspersa* and *Zonites Alge-rius*. All the animals subjected to a prolonged and exclusive diet of white lead or acetate of lead with flour (in equal proportions), presented, after a month, the phenomenon of accumulation in the liver, but besides this deposit, which the author calls normal, there was an abnormal deposit, very abundant, comparatively, in the cerebroid ganglia, and strikingly constant. These masses have, in the physiological state, a pale appearance; after the accumulation the colour passes to a well marked black, owing to the formation of a sulphuret of lead. 'This fact appears to me to have important consequences. Physicians might take advantage of it to establish the true etiology of saturnine encephalopathy, a disease well known in man, and in which the presence of lead in the brain has only been a strong presumption, the proof from analysis not being absolutely established; and for the biologist these facts are not less interesting, inasmuch as they seem, from a morphological point of view, to justify the comparison which has given to the upper nervous masses of the œsophageal ring the name of cerebroid ganglia. It is to be remarked that these ganglia, first of all, play the part of accumulating bodies; that they alone give rise to sulphuret of lead; that, at the least, they are the first to turn black, if it be the case that prolonged experimentation produces the same phenomenon in other nervous centres—a question not yet settled. Connect with this fact the general agreement in admitting in the case of the higher vertebrates (man especially), the indemnity of the cerebellum from plumbic contamination by accumulation (all the reliable analyses of saturnine brains hitherto seem to prove it), and we are authorised to ask if it may not be inferred that the subœsophageal ganglia may be considered, morphologically, as the analogues of the brain of superior animals. The affirmation is seductive; but then the disappearance of the commissure which unites these organs to the inferior ganglia (which become comparable to the cerebellum) being an index of superiority, it would be necessary to suppose that the Acephala (*Pecten*, etc.), in which this coalescence of ganglia is most common, are also higher in organisation than many of the Gastropoda; and this consequence could not be admitted

without discussion. Evidently, the question raised by the phenomenon of localisation cannot be fully answered without the aid of direct experimentation and of comparative anatomy.'

M. Heckel next describes experiments made with Cephalopoda and Gasteropoda. He put some of them into an aquarium, the water of which was renewed daily, and for three months gave them madder in a mixture of which flesh was the base. In no case did he obtain coloration of the internal shell; but it was quite otherwise with the cephalic cartilage and all the cartilaginous parts of the skeleton of these molluscs; these osseous pieces were coloured distinctly red. Hence it is necessary, he says, to distinguish clearly in molluscs, notwithstanding common interior position, between the hard pieces belonging to the skeleton and those belonging to the shell. All tends to indicate a morphological difference between these organic productions, which are distinct, besides, in chemical composition.

ALEX. B. MACDOWALL.

LUYS ON THE PHYSIOLOGY OF THE BRAIN.—In a treatise on the 'Physiology of the Brain,' just published, Dr. Luys, of the Salpêtrière, says that the activity of the brain is governed by the same laws and the same conditions of the organic mechanism which preside over the activity of the different segments of the spinal axis and medulla oblongata. Its activity is decomposable into a series of reflex processes, which are evolved as a result of the reaction of the preformed organic substratum and the natural play of the various forces excited to activity. Every reflex process is composed of three successive periods intimately connected with each other; a period of incidence, an intermediate period, and a period of reflexion. The first is always an impression irradiated from a sensory plexus, a centripetal impression, conscious or unconscious, and marks the *début* of the whole phenomenon, and it is always an attendant or satellite motor reaction that completes it. In the brain, as in the spinal cord, there is a system of zones or cells disposed for the reception of centripetal impressions, and a system of zones disposed for the emission of motor excitations. These two systems constitute a complete whole, and a veritable dynamic unity, across which the nervous currents are propagated. Physiological research shows that it is in the networks of the cortical substance of the brain that sensory impressions of all kinds reach their ultimate stage, taking from this point a new form, and becoming transformed into psychical citations, which again lead to movement. The networks of the cortical substance therefore represent a vast common reserve for all impressions belonging either to animal or to vegetable life; and in a physiological point of view a synthesis of all the partial sensibilities of the organ, *i.e.* the *sensorium commune*. On the other hand, the experiments of Flourens and Ferrier have shown that there exist in the cortical substance of the brain a series of isolated and independent motor centres governing certain groups of muscles. A cerebral reflex process differs from a spinal one, in its being amplified and transformed by the proper action of the exclusively cerebral nervous element interposed in its course. After dealing in detail with the several stages of the reflex processes taking place in the brain, Dr. Luys remarks that the action of emitting voluntary articulate sounds—speech—presents in its physiological evolution the highest expression of cerebral activity.

It is decomposable, like all the dynamic manifestations of the same type, into a series of successive and intimately associated phenomena. The processes which constitute it may be stated thus: first, a period of incidence which corresponds to the arrival of the acoustic impression, and its diffusion in the regions of the brain specially destined to receive it; secondly, a period of propagation during which the molecular changes or vibrations reach the purely intellectual regions, and lead to the participation of the conscious individual; thirdly, a period of reflexion, in which the excitations in their primordial succession, after being propagated throughout the whole extent of the cortical network, and having excited the active forces of its elements, are exported outwards as a synthesis of multiple activities, and pass into the region of automatic activity, which then translates them into precise articulate sounds. Speech essentially results from the synergic action of a psycho-intellectual and of an automatic sphere of nervous activity, the former comprehending the affection of the sensorium and subsequently of the conscious individual, the latter embracing the integrated and co-ordinated translation of the sensorial excitation. Anatomically, this last commences in the deep zones of cells of the cortex of the brain, and is conducted through the whole cortical striated fibres, then through the grey substance of the corpus striatum and of the pons, and terminates in the nuclei of origin of the hypoglossal and spinal nerves, which convey the impulses to the muscles affecting phonation.

LECOMTE ON ROTATION OF THE HAND.—The common theory of the rotation of the hand is, that the radius alone moves around the ulna in the rotation of the forearm and hand. Dr. O. Lecomte contests this view, and in an article in the *Archives Générales de Médecine* maintains that the rotation of the forearm and hand is executed by the simultaneous, harmonious, and similar movement of both bones of the forearm, the radius and the ulna; and that the rotation of the hand is not an unique movement. One principal mode of rotation may be admitted around a median axis, which is the prolongation of the line of the third metacarpal bone and middle finger; but the axis of this movement may be displaced either inwards or outwards, and thus secondary modes of rotation of the hand are produced around axes passing through each of the other fingers or the intermediate spaces. The play of articulations in the movements of rotation is very complex. At the elbow, notably, the humero-cubital articulation plays an important part. The ulna executes on the trochlea of the humerus a movement of spiral torsion, which may vary in extent, but which is present in all the modes of rotation. The system of the rotator muscles of the hand comprises four muscles; two for the radius, two for the ulna. Each of these bones has a pronator and a supinator. There are a radial pronator (the pronator teres); and a radial supinator (the supinator brevis); an ulnar pronator (the anconeus); and an ulnar supinator (pronator quadratus).

LÖWENBERG ON THE EFFECTS OF THE DIVISION OF THE SEMICIRCULAR CANALS OF THE EAR.—In Dr. Knapp's *Archives of Ophthalmology and Otology* (vol. iii. no. 2), Dr. Löwenberg, of Paris, gives the results of a series of researches on

the effects of division of the semicircular canals. Flourens observed some peculiar derangements of motion in animals in which he had cut these canals, chiefly consisting in rotatory movements of the head and of the body. Löwenberg, in repeating these experiments, satisfied himself that accidental injury of portions of the brain cannot be considered as constituting a cause of these phenomena. In his experiments the knife was carried into the tympanum forwards and upwards. There immediately followed the characteristic movements of the head from right to left, and in addition the 'mouvements de manège.' The right ear seemed to have lost its hearing power. The 'mouvements de manège' continued for several days, but diminished in intensity during sleep. If the animal were shaken or struck they increased in violence. On the third day the animal was killed. The dissection showed that while the right auditory nerve was almost completely divided, at the same time the semicircular canals of this side were partly crushed. This occurred in all cases. The substance of the brain was not injured; vomiting was not observed; derangements of motion only occurred when the injury was unilateral. He arrives at the following conclusions. 1. The derangements of motion are the result of irritation of the membranous canals and not of paralysis. 2. The irritation of the semicircular canals produces the convulsive movements reflectively, without participation of consciousness. Consciousness participates in these effects only in so far as it gives rise to renewed irritation by inciting the animal to voluntary movement. 3. The communication of reflex excitation from the nerves of the membranous semicircular canals to the motor nerves takes place in the thalamus.

MATERIA MEDICA AND THERAPEUTICS.

BALFOUR ON THE TREATMENT OF DIABETES.—At the meeting of the Edinburgh Medico-Chirurgical Society, on July 15 (*Edinburgh Medical Journal*, September, 1874), Dr. G. W. Balfour remarked that in November, 1871, he had read to the society an account of seven cases of diabetes mellitus, treated with more or less success by diet of skimmed milk and animal food, with full doses (three to nine drachms daily) of lactic acid (see *Edinburgh Medical Journal*, December, 1871). He now gave a history of the result in several of the cases.

Case 1 was phthisical, and died while under treatment, as noted at the time, after considerable improvement, which lasted three months.

Case 2. D. H., aged fifty-three, came under treatment weighing 8 stone 8 lbs., and after four months' treatment left, weighing 11 stone; three months subsequently he presented himself at the infirmary, still fat and well, weighing 12 stone, 3 lbs., using a mixed diet, and his urine free from sugar. He has not since been heard of, and is not known at his former address.

Case 3. M. E., aged fifteen, when first seen weighed 4 stone 11 lbs.; after four months' treatment she weighed 5 stone 10 lbs., but was unable to take mixed diet without a reappearance of the sugar. She left improved, but returned about a year later, worse; again improved, and was discharged, and was finally readmitted in October, 1873, still labouring under diabetes, and again much emaciated. She

died a few days after admission from gangrene of the lung, apparently induced by cold caught on her journey to the infirmary.

Case 4. A. M., aged twenty-five, improved greatly, but was wholly lost sight of after only two weeks' treatment.

Case 5 was benefited by the treatment, but had to be dismissed for neglect of rules.

Case 6. M. W., aged seventeen, weighing 5 stone 2 lbs., continued to improve in health and weight for many months. She first came under treatment on November 3, 1871, and a year afterwards she had gained one stone and a half, having in the meantime passed through an attack of small-pox, and also one of acute rheumatism; the latter not only came on while she was using the lactic acid, but was also recovered from without the acid being given up. While on her diet of milk, meat, and green vegetables, her urine remained free from sugar, but she was unable to use any starchy article of diet without a recurrence of sugar in her urine. She subsequently became phthisical, and died last winter.

Case 7. R. A., aged thirty-five, weighing 8 stone 11 lbs., improved very much under treatment, gained about a stone in weight, and remained free from sugar as long as he avoided any dietetic imprudence; he led an active and exposed life, and died about a year after coming under observation, from an attack of pneumonia caught while on a journey.

Dr. Balfour remarked that these were very serious cases, and the great improvement which they all made under treatment, and the apparent cure of one of them, seemed a sufficient guarantee of the importance of lactic acid as a treatment for, at least, a certain class of diabetics; viz., those in which the disease, or its more important symptoms, depend upon diminished combustion, characterised by weakness, emaciation, and a low temperature. Dr. Balfour had treated many other patients in the same way, always with a certain amount of success, and in some the success had been very gratifying. The fact that the girl (in Case 6) got rheumatism whilst using the lactic acid would seem to confirm Dr. Foster's view, that there is a risk of this treatment inducing that disease; out her recovery from the rheumatism without giving up the acid, indicated that in her case the rheumatism and lactic acid were not connected as cause and effect. Dr. Balfour had never seen rheumatism dependent upon the use of the lactic acid, but had been informed of one case, besides those recorded by Dr. Foster, in which this disease invariably occurred whenever the acid had been used for only a short time; so that this effect of the acid seemed to be real in certain constitutions, but this must be of rare occurrence.

There is another form of diabetes characterised by increased transformation of glycogen within the liver, which goes on even when the patient is restricted to an exclusively flesh diet. Such patients have a normal temperature, and maintain their plumpness and ruddy countenance long after they have displayed unequivocal symptoms of this most serious disease. But the increased transformation of glycogen into sugar in the liver is believed to depend upon a relative increase in that organ of the blood-ferment which promotes this change. Accordingly, several months ago, Drs. Ebstein and Müller, in Breslau, proposed to employ carbolic acid to prevent this change and to cure the disease, and they have published a couple of cases in which very great improvement followed the use of carbolic acid

in doses of about six grains daily, and in one of them the diet was a mixed one throughout (*Berliner Klinische Wochenschrift*, December 8, 1873; see also LONDON MEDICAL RECORD, February 11, 1874). Dr. Balfour employed the carbolic acid in several cases, sometimes in more than double the doses recommended by these authors, but without much benefit. In one case, the sugar, after a time, did disappear; but as the patient was dying of phthisis, and died a few days subsequently, it may be doubted whether the disappearance of the sugar was due to the carbolic acid. The acid may be given in pills made with liquorice powder, and seems worthy of further trial.

PUBLIC HEALTH.

THE GERMAN PUBLIC HEALTH ASSOCIATION.*

The second annual meeting of the Association was opened on September 12, by chief Burgomaster Von Winter, in the hall of the old Franciscan monastery at Dantzig. This city was chosen as the place of meeting, on account of the great amount of sanitary work that has been done there in recent years in regard to water-supply, drainage, irrigation of fields, etc.

The Association has already spread over the whole of Germany, and numbers 552 members. Burgomaster Dr. Erhardt, of Munich, was chosen president, and Privy Councillor Günther, of Dresden, and Commerce-Councillor Bischoff, of Dantzig, vice-presidents.

The proceedings were commenced with a report by Dr. Strassmann, of Berlin, on the subject of the Demands of Public Health on the Police of Buildings (*Baupolizei*). The condition of Berlin as regards buildings has become much worse during the last twenty years, through greedy speculation. In the present day, those who undertake to erect buildings strive only to thoroughly use up all the available building-ground, to use every corner that is but just suitable, and to establish as many extra rooms as can be let. Hence in Berlin the type of lodging-cellars prevails. Within three years the one-storeyed houses in Berlin has decreased eight per cent., the two-storeyed three per cent., and the three-storeyed one and a half per cent.; while the four-storeyed houses have increased eleven per cent., and those with five and more storeys forty-three per cent. The houses having open frontages with cellar-dwellings have increased fourteen per cent., and the dwellings in courts have increased from 6,937 to 7,204, or four per cent. It has been shown by statistics, that the height of lodgings has always a great influence on the health of the inmates; and in the new parts of the town the unfavourable conditions of building development have greatly increased. The lodgings on the fourth and higher storeys show a death-rate exceeding that of the cellars, namely, 2.6 to 2.9 per cent. Of the lodgings, 60,000 are overcrowded; and 200,000 persons have to live in lodgings with only one room that has a fire-place. When, in addition to this, we take into account the bad water-supply and drainage, and the pest-exhaling gutters, with a

* From the *Allgemeine Medicinische Central-Zeitung*, September 19, 23, and 26, 1874.

water-surface of 721 acres, it is not surprising that, next to that of New York, the death-rate of Berlin is the worst. There is already one death in 30.5 inhabitants. Among the 27,600 deaths last year, 11,000, or two-fifths, occurred in children. The reporter summed up his opinion as follows. 1. Settlement in the neighbourhood of towns ought to be encouraged. 2. In the new parts of towns, a system of water-supply corresponding with the demands of public health should be established. 3. The erection of detached buildings and groups of buildings should be promoted. 4. In streets which are not principal thoroughfares, there should be a moderate width of road. 5. The height of buildings should not exceed the width of the street, and in no case should be greater than four storeys, including the ground-floor. 6. One-third of each piece of building ground should remain free from buildings. To these conclusions another was added by the joint reporter with Dr. Strassmann, Herr von Haselberg, who at the same time agreed with his colleague's opinions, viz.: 7. Lodging and sleeping rooms, the floor of which lies entirely or partly below the level of the surrounding soil, should only be allowed if they at least answer to the conditions laid down for lodgings with regard to their water-supply, their situation above the highest level of ground-water, their height as to light and ventilation, and the lateral separation of their walls from the soil. Individual places, however, may make further regulations regarding cellar-lodgings, or may prohibit them altogether.

After discussion, the Congress decided to abstain from passing definite resolutions on the subject, but to defer the decision on the whole question to the next meeting.

Dr. Schwabe, of Berlin, made a communication on the Influence of various Lodgings on the Health of the Inmates, so far as can be ascertained by Statistics. The following were the conclusions at which he arrived. 1. The death-rate is greater in cellar-lodgings than in any others. 2. Epidemic diseases prevail more severely in cellar-lodgings than in any others. 3. Among epidemic diseases, diarrhoeal affections occur with greater intensity on the ground-floor.

The Association agreed in general with these deductions, but decided to abstain from passing detailed resolutions, and to appoint a referee who should report on the question, and collect and compare the sanitary regulations affecting cellar-lodgings in the most important large towns, with the view of framing a general code of regulations.

At the meeting on September 14, Dr. Sander, of Barmen (in the place of Privy Councillor Esse, of Berlin, absent through illness), presented a report on the question: What are the Reasons for, and what against, the Assembling of Different Kinds of Diseases in the same Hospital? The reporter described the first traces of the care of the sick in ancient times; and then passed on to the middle age, with its leper-houses, pest-houses, etc. The Church was rightly credited with having systematically carried out the care of the sick. Hospitals proper dated first from the ninth century. To Pope Innocent III. was due the merit of uniform organisation, for hospitals were erected everywhere after the model of the Santo Spirito, and were soon known by the name of Hospitals of the Holy Ghost. In the last century, Frederick I. founded the Charité in

Berlin, and Joseph II. the Allgemeine Krankenhaus in Vienna. In France, Louis XIV. founded hundreds of hospitals after one plan, one like another. The results could not be lasting. Dr. Sander drew a picture of those hospitals from Tenon's work. The vast wards were quite crammed with beds; it was never considered necessary to make provision for free space; and in each bed lay two, three, or even four patients together. Hence the enormous mortality in these wards. Very often, the patients lay outside the bed on benches, in order to be free from the kicks and blows of their fellow-sufferers; and, as patients suffering from infectious diseases were not separated from the others, it is not surprising that many, admitted into hospital with trivial diseases, died of the contagious disorders. In England, hospitals were and are for the most part the work of private beneficence. This has given rise to an immoderate development of specialities, of which the reporter disapproved; while, on the other hand, it has frequently produced irremediable mischiefs, in consequence of the benefactors of the hospitals, as patrons, holding the right of filling a certain number of beds as they please. There are in London special hospitals for all imaginable diseases, for diseases of the eye, throat, skin, and hip; hospitals for convalescents, for consumption, for diseases of children, etc. The most recent institution of the kind in London is a hospital for diseases of women, in which, it is said, the patients are treated by female physicians alone. Another English speciality is the hospitals for consumption. This excessive specialisation of hospitals the reporter regarded as in many cases useful, but necessary only in a few cases, and often even injurious. The results obtained in the small hospitals and in private practice appeared from statistics to be not better than in the naturally well-regulated large hospitals. The reporter regarded the facts hitherto adduced in support of the opposite opinion as much too scanty to allow any fixed conclusions to be drawn from them. All the so-called hospital diseases occur in the same way outside hospitals; and neither small hospitals nor private practice possess any advantage which cannot be obtained in the larger institutions by proper hygienic management. Dr. Sander regarded special hospitals as necessary only for cholera, small-pox, and epilepsy. For cholera and small-pox especially, provision is made by the erection of barrack-hospitals, as has been done at Moabit near Berlin. The reporter pleaded in favour of the system usual in Germany, of giving the hospitals a communal or parochial character. The ordinary practice there of erecting permanent institutions in the form of barracks for small-pox and cholera alone, and, as regards other diseases, abstaining from forced specialisation, he regarded as the only correct plan. The hospitals should be general; and isolation should be carried out only so far as was demanded in the interests of the public.

The discussion which followed was on the questions of the greater utility of large or small hospitals, the isolation of cases of infectious diseases, etc.

Dr. Börner, of Berlin, spoke in favour of the erection of small hospitals. Granting, he said, that the statistics of hospitals rested on a very inferior and incomplete foundation, it was to be observed that it was very difficult to distinguish between what was absolutely established, what was only probable, and what was improbable or false. We could not escape from the necessity of using a strictly scientific

method, but the carrying out of practical regulations could not wait for this. This was applicable to statistics as the indispensable basis of public hygiene. If they did not give a sufficient answer, if their material was still imperfect, we must be content with taking as a foundation the more general facts and those theories which were recognised as correct. Long before statistics had brought together the figures which showed to large towns their sanitary dangers, public hygiene had recommended a number of regulations which ultimately proved to be perfectly correct when tested by statistics. This was the case with drainage, of the favourable influence of which on mortality, accurate statistics were still wanting. Under all circumstances, the assumption that smaller hospitals were most advantageous was, in his opinion, not set aside by the want of statistics. He was convinced that small hospitals, capable of holding from 150 to 200 beds, were to be preferred to larger ones. The physician having charge of the cases must stand absolutely at the head of the hospital; and this could not possibly be carried out in hospitals with more than 250 beds. The statistics of military medicine, the only statistical information in Prussia as regards hospitals, might furnish some important contributions towards the settlement of the question, if it should be established that the mortality in the small garrison hospitals was less than in the large ones; this would be of special importance, as the patients treated in them would afford material of a tolerably uniform kind as regarded age, constitution, etc. Since the war of 1870-71, a similar view had gained ground in France. In the commission on the new Hôtel-Dieu in Paris, such men as Trélat, Broca, and Vidal, had expressed themselves in favour of small hospitals.

General-Surgeon Roth, of Dresden, remarked that the differences between individual garrisons were much too great to allow any statistical conclusions of value, as to the relative results of large or small military hospitals, to be drawn from them.

Privy-Councillor Varrentrapp, of Frankfurt, spoke in favour of small hospitals; laying special stress on the circumstance that in them alone medical direction could be carried out.

The discussion ended with an expression of opinion that the medical and the scientific decision of the question under consideration were still too divergent to allow any fixed conclusion to be drawn.

Dr. Hirt, of Breslau, presented a report on Female Labour in Manufactories. While in general numerous causes of disease existed in the various kinds of industrial occupation, this was the case in a much higher degree as regards women. While the healthy woman required for herself a greater amount of protection than the man, this protection was in a special manner required for pregnant females employed in factories. For the protection of the latter, the speaker demanded general legal regulations. Long continued exhausting labour, machine-sewing, etc., were known to produce abortion; and this was also caused by working in certain poisonous materials, viz., lead, phosphorus, mercury, anilin, arsenic, and copper. Of 140 pregnant women working in lead, 82 had abortion, or 58 per cent. Statistics showed similar results with regard to mercury, arsenic, and anilin. It was further established that the action of these poisonous matters was communicated from the organism of the mother to that of the child. In

1,000 cases of female lead-workers, 785 had stillbirths; and in addition, 40 per cent. of their children died within the first, and 30 per cent. within the second year. The annual mortality among children of females employed in coating mirrors was 65 per cent. In normal conditions, the mortality of children in the first year was only 20 per cent., and even in large towns it was not higher than 20 or 25 per cent. Again, the female labourers referred to were much too imprudent after their confinement, and were in too great haste to return to work. Hitherto, unfortunately, legislation had afforded no protection, either in England, France, Austria, Germany, or Belgium. Switzerland alone had made a beginning, and must be an enlightening example to Germany. The humanity of the house of Dollfuss, in Mühlhausen, was also worthy of mention, where full leave of absence was allowed to all the pregnant females for three weeks before and three weeks after confinement. The reporter summed up as follows. 1. Pregnant women should be interdicted during the second half of pregnancy from employment in all branches of industry where poisonous materials are used; as, for example, the manufacture of coloured papers and artificial flowers, the coating of mirrors, the manufacture of caoutchouc articles, etc.; and they should also be excluded from factories where injurious gases abound. 2. No puerperal woman should be employed in any manufactory before the ninth day after her confinement. 3. No puerperal woman should be employed in a factory where poisonous materials are used before the forty-second day after her delivery.

These conclusions were received with lively approbation. The Association, however, abstained from passing a special resolution, but left it to the individual members to work out the ideas in their respective districts.

At the meeting on September 15, Professor Reichardt, of Jena, read a report on the Supply of Water from Springs and Rivers. He said that the evil influence of bad drinking-water was well known. Drinking-water should not only be pure, but its quality should be, as far as possible, uniform; for sudden changes in drinking-water were injurious to health. River-water never afforded an useful drinking-water, as it was subject to many alterations, and changes of temperature, local admixtures, and many processes of decomposition; while in spring-water the variations in composition, hardness, etc., are quite unimportant. It should, therefore, be the duty of the communes to endeavour to procure a supply of spring-water; if this were absolutely unattainable, river-water was in general preferable to pump-wells. In spite of filtering, etc., however, river-water remained only mechanically, not chemically purified. If the use of river-water could not be avoided, it was recommended not to take it direct from the rivers, but to use that which had passed for some distance through the layers of the alluvial soil. On the whole, however, it might be assumed that, as was the case at Vienna and Frankfurt, other towns ought properly to be able to derive their water-supply from springs.

The joint referee, Engineer Schmick, of Frankfort-on-the-Main, arrived at the same result from a technical examination of the question. The quality and purity of spring-water were dependent on the nature of the layers of earth through which the water passed. The thinner these layers were, the less was their

power of purifying the water; besides, in consequence of the solvent action of the water, there was not only mechanical but chemical impurity. Besides the quantity of the springs, their quality also must be ascertained by geological examination. The conditions of a good water-supply might be treated from three points of view. The first was the quality of the water, the conditions of which the reporter fully described; it should not only be fit for drinking but also for cooking purposes. With regard to the second point, that of quantity, it was a subject for consideration whether all the water supplied to a town should be of the same kind, or whether there might be separate supplies for houses and for industrial purposes. With regard to the locality of the water, it should be supplied to all storeys with a certain excess of pressure. The supply of river-water should be unconditionally rejected; and so should also the supply of 'ground-water,' which, in regard to quantity, was the most uncertain of all supplies. On the other hand, the storing of rain-water, as in England, possessed many advantages. Still, the water-supply from springs remained the hygienic ideal. Investigations on this subject would certainly show that many towns, hitherto unaware of the fact, possessed good springs. In Brunswick there was a project for obtaining a supply from the Harz mountains, not only for the town, but for the whole state.

In the discussion, the speakers supported the principles followed in their different towns. Medical Councillor Günther, of Dresden, approved of the use of 'ground-water,' which had proved very good there; while Dr. Sander supported the plan of supply from rivers. The question having arisen what was to be understood by the word 'spring' (*Quelle*), it was remarked that the so-called 'ground-water' supply in Dresden was merely a supply from springs—the 'ground-water' being only the overflow from subterranean springs.

A report was presented by Chief Burgomaster Jäger of Elberfeld on the question: What has been the result of the Law of March 18, 1868, on the Erection of Public Slaughter-Houses? As yet, no definite conclusions could be arrived at as to the operation of this law; but it had been ascertained from inquiries in Liegnitz and Solingen, as well as in Bavaria, Baden, Austria, etc., that the butchers had been able to bring forward no valid objections against the regulation of slaughtering. The further consideration of the question was deferred to the next meeting of the Association.

The Association appointed a Commission to examine each of the questions laid before the meeting, especially that of the statistics of lodgings, and to collect and arrange statistical matter. The meeting was then closed.

The Congress is to meet in 1875 in Munich.

OBSTETRICS AND GYNÆCOLOGY.

FANNY AND CHARRIER ON HYDRATE OF CHLORAL IN PUERPERAL ECLAMPSIA.—M. Fanny, in a thesis published in 1874 (*Revue des Sciences Médicales*, July), records several cases of puerperal eclampsia treated by chloral. The patients were admitted into the maternity wards of the Charité

and Cochin Hospitals. Hydrate of chloral was administered both internally by hypodermic injection, and was introduced into the stomach and rectum. In one case a subcutaneous injection of hydrate of chloral was given by means of a large Pravaz's syringe. Five hypodermic injections were given to this patient without any ill consequences to the subcutaneous cellular tissue.

The two following statistical statements are extracted from M. Fanny's thesis.

1. Chloral given after other preliminary treatment, bleeding, leeches, purgatives, revulsives, anæsthetics, etc.; women treated, 16; cured, 14; died, 2.

2. Chloral given alone: women treated, 20; lost sight of, 1; cured, 19.

The results obtained by the use of this agent are, therefore, very encouraging, and M. Fanny believes himself authorised to draw the following conclusions: Hydrate of chloral affords, at the present time, the best treatment for puerperal eclampsia. It is indicated not only when the attacks openly declare themselves, but also when any symptoms suggest coming trouble.

Dr. Charrier's case, published in the *Annales de Gynécologie* for Jan. 1874, is also strongly in favour of the use of chloral in puerperal eclampsia.

A young woman, the daughter of neuropathic parents, suffered two attacks of puerperal eclampsia, in the middle of the ninth month of her pregnancy. Two injections, each containing four grammes of chloral were given to her. On the occasion of a third but slight attack, a third injection of two grammes of chloral was administered. Dr. Charrier induced premature labour by dilating the os uteri by means of India-rubber bags filled with tepid water. The mother and child were in good health when this case was published. The child, when two months old, had three eclamptiform convulsive attacks; four small teaspoonfuls of syrup of chloral were given, and the attacks never reappeared. E. LAWSON.

ENGELMANN ON PROLAPSE OF THE UMBILICAL CORD.—Dr. Geo. Engelmann, of St. Louis, contributes to the *American Journal of Obstetrics*, August 4, 1874, a paper on this subject. He says that the causes of prolapse of the umbilical cord have mainly proved to be such circumstances as prevent the complete filling of the pelvic brim, and the close adaptation of the lower segment of the uterus to the presenting part. One of the more important of these circumstances is the shape of the foetal part itself, and thus foot-presentations are more frequently complicated by prolapse, whereas vertex presentations are least threatened. The foetal appendages are of secondary and minor importance; undue length of the cord, its marginal insertion or attachment of the placenta low down in the uterus, can never be direct cause of the accident; excess of liquor amnii is alone to be feared.

Some stress is to be laid on abnormality in shape and position of the womb, much more upon twin-births. More dangerous than any of these is the contracted pelvis, which Dr. Engelmann proved by measurements and numbers to be the main cause of prolapse of the funis, directly and indirectly. Primiparæ are, comparatively speaking, almost as frequently afflicted as multiparæ.

The *post mortem* examinations revealed only the lesions due to death from asphyxia, nothing characteristic for death caused by prolapse of the cord.

The prognosis is somewhat better than generally allowed; most favourable for foot-presentations, while vertex-presentations are more dangerous than any; the case being, under all circumstances, more threatening when occurring in a primipara.

In the treatment the postural method is important, more as an adjuvant, however, than as a method in itself of dealing with the prolapse.

Version is comparatively the most successful of all operations, and should be more frequently resorted to when any choice of method is given, as in head-presentations; the application of the forceps and reposition of the cord are less to be relied upon; but, whatever may be the course determined upon, it must be borne in mind that the success of all operations by which we seek the preservation of the child whose life is threatened by compression of the prolapsed cord is in a measure dependent upon the judicious use of chloroform, and its application to full surgical anaesthesia.

OPHTHALMOLOGY AND OTOLOGY.

SCHIESS-GENEUSEUS ON THE THERAPEUTICS OF MYOPIA.—The *Annales d'Oculistique* (July and August, 1874) contains a most interesting paper, which was written to show that the classic definition of myopia by Donders—to the effect that it is always associated with an elongation of the axis of the eye—is too restricted, although Donders at the same time allows that the higher degrees of myopia may be attended with spasm of the accommodation. To M. Dobrowolski is due the credit of showing that, in a large proportion of cases of myopia of low as well as of high degree, this factor or 'cramped accommodation' must be taken into consideration, and may be eliminated by the use of atropine; and both he and Liebreich have called attention to the apparent development of myopia in eyes which were undoubtedly hypermetropic. The result of a series of observations by Schiess-Gemuseus is to show that not only in emmetropia, but also in hypermetropia, a real myopia may be acquired. The maxim that myopia is incurable has become so deeply rooted, that all treatment is looked upon as of little value, and any opinion to the contrary carries but little weight. One difficulty which besets any treatment of the affection in its early days, is the absence in many instances of any subjective symptoms; for it is generally the friends of the myope who first notice any impediment to vision. The subjective symptoms, when they do appear, are well known—a certain aversion to light, and a feeling of uneasiness which at times amounts to actual pain; and these are associated with a spasm of the accommodation, with ciliary congestion, and with lacrymation. With the ophthalmoscope, a constant feature in commencing myopia is a decided redness of the optic disc, more especially on the nasal side, and with this hyperemia there may be some haziness of outline as well; at a later period these appearances will be followed by pigmentary changes in the surrounding choroid, which, when more advanced, will assume the well-known features of atrophic crescents. These same appearances have been noted by several in the eyes of hypermetropes, who work without any assistance from glasses. The author of this paper believes that

in these two opposite conditions of refraction, one and the same cause is at work—excessive action on the part of the ciliary muscle, and consequent congestion of the choroid and of the retina; so long as the mischief goes no further than congestion, the tissues may regain their natural appearance, but when structural change has once set in, this is no longer possible. It is probable that when the optic disc has become hyperemic there is some congestion of the choroid as well, but it is not then appreciable with the mirror, and it is not sufficient to cause any atrophic change. Distension of the veins, with a curvature of the arteries, is also met with in these early days of the affection; similar appearances may be seen in the asthenopia which is the outcome of hypermetropia.

Schiess-Gemuseus asserts that the commencement of myopia is associated with a spasm of the ciliary muscle, a condition which predisposes to sclerоchoroiditis, for it has been shown by Hensen and by Volkers that efforts in accommodation cause a real movement of the choroid; and all observers agree that during accommodation a larger quantity of blood is admitted within the eye—a condition in itself predisposing to inflammation, especially in young subjects. Why, however, the stress of the inflammation and the subsequent atrophy should fall upon the neighbourhood of the yellow spot, is not at all satisfactorily made out to the author's mind.

Granting the correctness of his assertion, that non-congenital myopia is generally associated with spasm of the accommodation, it is natural to suppose that the use of atropine would be attended with direct and very beneficial results, and this is so. The result of his observations is to support very conclusively the assertion of Dobrowolski, that a large percentage of cases of myopia of low degree are dependent upon ciliary spasm, and can be cured; that, in cases of high degree, the myopia will be very decidedly lessened; while there will still remain a certain number of cases where the myopia is extreme, and where the structural changes are so marked as to forbid the hope of any improvement from the use of atropine.

The result of this plan of treatment in one hundred and one myopic eyes was to show that spasm existed in eighty-five cases, while in fifteen cases no spasm could be detected. In one case, an amount of accommodation equal to one-eighth was released. These figures agree in the main with those published by Dobrowolski and by Hosche. In the slighter degrees of myopia, the effect of the treatment was more marked than in those of high degree. The use of atropine was persisted in for some weeks, and was generally accompanied with protective-glasses, and the observations were made and recorded when the accommodation and the pupil had regained their natural condition. The spasm did not reveal itself equally soon in all cases, nor did it yield with the same rapidity in every instance.

In his concluding remarks, the author warns us that we have no right to expect a specific against myopia in the sense that quinine is a specific for ague; but just as phthisis in all its forms was considered incurable, so it is unscientific to regard all cases of myopia as alike, and as incurable. The result of doing so has been that patients have resigned themselves to perpetual loss of vision, and that surgeons have contented themselves with stereotyped and half-hearted directions, which in many cases have been but half carried out. If the plan of

treatment by rest and atropine be tedious and irksome, yet, if the patient be made to understand the principle upon which it is recommended, he will in most instances readily allow himself to be placed under any discipline which holds out a reasonable hope of better sight.

SAVARY ON A CASE IN WHICH A FOREIGN BODY REMAINED FOR FIVE YEARS IN CONTACT WITH THE IRIS WITHOUT EXCITING SYMPATHETIC OPHTHALMIA IN THE OTHER EYE.—In the *Annales d'Oculistique*, July and August, 1874, Dr. Savary (du Mans) describes a case which occurred in his own practice, that of a French lady, aged fifty, who had met with a severe fall five years previously, her foot tripping upon a hard road. She was much injured by falling upon some flints. The left eye was seriously injured, but the exact nature or seat of the hurt was not very clearly made out, although she underwent much active treatment at the time; for four months there was continued pain, at the end of which the eye, while it retained its shape and form, was quite blind. After a period of three years the pain returned, and Madame R. sought further advice at the hands of a surgeon, who detected the presence of a foreign body within the eye, and who made an ineffectual attempt, though in what way is not clear, to remove it. After another fifteen months, and after much pain, Madame R. applied to Dr. Savary, who found the pupil of the left eye fixed by adhesions, and blocked up by pigmented membrane, through which the opaque lens could be made out. Within the anterior chamber was a greyish white substance, adherent behind to the iris, and in contact with the cornea in front. This substance filled the lower part of the chamber, and the cornea over it was hazy, and presented the mark of an old horizontal scar. The globe was soft and painful on pressure, and the ciliary congestion and intolerance of light were excessive. The right eye was in every respect normal.

The diagnosis was that, in all probability, a fragment of stone was imbedded in the anterior chamber, although it might well be that the case was one of cyst of the iris from excessive exudation; in either case some interference was called for, but there would very likely be a difference of opinion as to whether some attempt should be made to find and to remove the foreign body, or whether an abscission or even the removal of the entire eye was advisable. It was determined to search for the foreign body, although the dangers and the difficulties of operating upon a globe, which was disorganised by prolonged inflammation, were obvious, and not underrated. The attempt was, however, made, and without chloroform. The cornea was incised at the periphery, and a foreign body, encrusted with exudation, was readily detected, and extracted with the forceps. There was no prolapse of iris, and but a slight amount of bleeding into the chamber. The pain subsided in a few hours, and when the dressings were removed the following day, the wound was quite healed, and without undue reaction. At the end of a week the eye was quite quiet, and the patient was convalescent, and able to leave the hospital free from pain, and from all inconvenience, the eye of course, remaining quite blind. The question of determining the existence of a foreign body is surrounded with difficulty, and the writings of our foremost ophthalmic surgeons give very uncertain advice as to the proper course to pursue when there is only a probability that a foreign body

has remained within an injured eye. There are some who would wait the appearance of symptoms of irritation, while there are others who would at once remove an eye which was injured to a degree which would interfere with vision, quite apart from the existence of a foreign body within it. Probably these two extremes of treatment are unwise, but it must be allowed that even at this time very many cases of sympathetic ophthalmia are met with which might well be prevented.

BOWATER J. VERNON.

MISCELLANY.

TREATMENT OF HOOPING COUGH.—M. Maximin Legrand, in the course of an account of a visit to the Hospital St. Charles, at Nancy, published in *L'Union Médicale* for October 8, refers to the successful treatment of whooping cough and hysterical coughs generally by sulphurous treatment. M. Parisot, the head physician of the establishment, gave him particulars of the case of a child who, twelve days after the whooping cough had declared itself, was placed in a sulphur vapour bath and completely cured. Wherever M. Parisot sees that the cough is taking on a convulsive character, he has recourse to the sulphur vapour baths, and almost invariably overcomes this distressing symptom. Passing from science to art, M. Legrand dilates on the beauty of the old earthenware vessels used in the pharmacy of this hospital. They were, it appears, given to the institution by King Stanislaus, and are in the best style of French pottery, that of Louis XIV., the most beautiful and characteristic of all the peculiarly French styles. M. Legrand adds that the pharmacy is kept with the most perfect neatness and order, and the precious jars are valued as they deserve to be.

THE LONDON SCHOOL OF MEDICINE FOR WOMEN.—On October 12 was opened the London School of Medicine for Women. The council had determined that no inaugural address should be given, and thus the day passed unmarked otherwise than by the fact that the first lecture was given in a medical school devoted exclusively to the teaching of the female sex. The staff of the school is composed mostly of gentlemen who are lecturers in other medical schools, and the list comprises names of well-known reputation among the medical and other scientific professions. The school is now in full working order, and women can receive an education fitting them to practice medicine. The services obtained by the development of this school need not stop short at preparing women for the medical profession. There are several branches of science allied to the study of medicine, such as chemistry, botany, comparative anatomy, etc., in each of which a course of lectures is given as part of medical education. A knowledge of any one of these subjects is attainable equally by women as by men, and there is no reason why women should not achieve a scientific reputation and earn a fair competency by engaging in these studies, and by imparting their knowledge to others.

DISORGANISATION IN THE PUBLIC SERVICES.—The greatest discontent prevails at the present moment both in the army and navy medical departments. The army medical department is now very greatly below its strength of a few years ago; the members are, therefore, so hardly worked, that an officer returning from a foreign station is sometimes obliged to go straight to home duty without leave of absence. The result of Lord Cardwell's changes has been to mulct the medical officers in forage, band, and mess-allowance, and to detach them from regimental connections. One officer has, we believe, had to incur the cost of thirty removals in two years. There are assistant-surgeons of over sixteen years' service who remain still in

the same grade as on the day when they entered the army; promotion is at a stand-still, and the retirement pay is insufficient to induce senior men to go. There are also serious complaints of the deterioration of the army hospital corps. Mr. Hardy, therefore, has his hands full. The state of the naval medical service is still worse. There is an absolute dearth of candidates, and a chorus of discontent from one end of the service to the other. Matters have indeed reached a point at which it is felt that some change for the better must be made. There are sixty vacancies and no candidates. Four young surgeons who have recently entered the navy have rather submitted to court-martial than remain in the service, and have thus insisted on making an ignominious exit, after their resignations had been repeatedly tendered and refused on the ground that 'their services could not be spared.' In no other branches of the public service could such a state of things be tolerated by public opinion, and it cannot be permitted to endure in this.

MR. STANSFELD'S FACTS.—It might have been expected that Mr. Stansfeld would have taken some pains to master the facts before committing himself to the attack which he made at Bristol on the legislation of his colleagues, Mr. Bruce and Lord Northbrook. His speech, however, shows a reckless disregard of them. He declared the Acts to be a failure in their object of lessening enthetic disease and diminishing the ratio of invaliding in the army. A reference to facts shows that, whereas the number of men sent to hospital with the constitutional and virulent form of enthetic disease, from the troops quartered in the districts now subject to the Acts, was 120 per 1,000 of strength in 1866, it fell steadily through 1867-9, to fifty-four in 1870; while, in the districts which never have been subjected to the operation of the Acts, the ratio in 1866 was ninety-nine, and has risen through 1867-9 to 113. It is by passing over such facts as these, that Mr. Stansfeld is emboldened to call the Acts a failure. They were enacted to lessen the loss of military and naval strength, consequent on the amount of sickness from enthetic disease, which equalled 1,500 soldiers, and the entire crew of one of our largest ironclads constantly off duty. They have reduced, in spite of many obstacles, the more important form of disease to one-half.

His next fact, when analysed, amounts to this: that the women immigrating into the 'subjected district' are found to suffer in a proportion four times greater than that of those residing there; and his easy declamation against the vicious tendency of the Acts is to be met by the fact that the streets of the towns under the Acts are more free from abandoned women enticing young men, than those of any other towns in England; that the number of such women in those towns has decreased from 3,400 to 2,100, and that 940 houses of ill-fame have been closed. Clandestine prostitution has been almost suppressed; and this has been made, strange to say, the subject of public and formal complaint by Mr. Stansfeld's female allies.

The close examination of the facts, indeed, tends to show more and more that these Acts are deserving of the most hearty public approbation, and have rendered the most important public service.

LONDON MILK.—Insufficient notice has been taken of the complaint recently made by the more respectable milk dealers to the London vestries, of the impunity in adulteration still largely accorded to the sale of adulterated milk by fraudulent dealers. We pointed out some time ago, and more than once, that the medical officer and inspectors almost exclusively confine their attention to the milk sold over the counter, while the public are most interested in the milk delivered at their houses. Few milk dealers are so unwary as to put adulterated milk on the counter. Almost as few, we imagine, supply unadulterated milk to their customers. The customary dodge of the milkman on his rounds is to refuse to sell milk to a chance customer, for fear that he should be the emissary of a sanitary inspector; but there are means of getting

over the difficulty. There are proper places for the activity of milk-inspectors which would be found very effective, in the streets, the railways, and the workhouses. We make bold to say that at least fifty per cent of the milk supplied at London houses, and of the milk sold by wholesale country dealers to small retail dealers at the railway stations, and supplied to workhouses, is adulterated. In connection with the milk tolerated, and even encouraged, at many public institutions, we may mention that the managing director of the Aylesbury Dairy Company has stated that he has repeatedly refused invitations to tender for the milk-supply, certain of knowing that the average price paid by such institutions is less than that of good country milk at the farms, and that the contracts were in fact, then entrusted to unscrupulous dealers to supply adulterated milk on a large scale with impunity. It will be remembered that the latest report on the milk-supply of the great metropolitan hospitals, which appeared some time since in the *British Medical Journal*, showed that every one of them was supplied with milk which had been either watered or skimmed, and in several cases subject to both operations; while Mr. J. A. Wanklyn's report to Mr. Roussel, superintendent of contracts, showed that the workhouses and public infirmaries were pretty uniformly in the same predicament. In this connection, it may be well to recall the well-established fact that the lactometer is an instrument perfectly useless for establishing the purity or quality of milk, and that the estimation of milk-solids, now a very easy and expeditious chemical process, is the only reliable test.

FEEDING-BOTTLES.

We have received from Mr. Mather, of Bath, one of the 'Princess' feeding-bottles, mentioned by Dr. Eustace Smith in his article upon 'Feeding-Bottles' in the *SANITARY RECORD* of September 19, as a bottle 'which, for elegance of design and accuracy of detail, cannot be surpassed.'

A careful inspection of this useful invention convinces us that it is simple and ingenious in its construction, and thoroughly adapted for the purpose to which it is to be applied.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17s. 4d.; free by post, 19s. 6d.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & Co., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The First Volume, containing upwards of Two Thousand Articles abstracted and compiled by a staff of Fifty Hospital Surgeons and Physicians, is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for the year 1873 are also ready, price 1s. 6d. each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & Co.—Calcutta: THACKER, SPINK & Co.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & Co.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & Co., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, NOVEMBER 4, 1874.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

VULPIAN ON THE VASO-MOTOR NERVES.

The lectures given last year by M. Vulpian at the Paris Faculty of Medicine on the vaso-motor nerves, have been recently published in a collected form by M. Baillière of Paris, under the title of *Leçons sur l'Appareil Vaso-moteur, Physiologie et Pathologie*.

These lectures contain but few original theories, but are therefore, perhaps, all the more instructive. M. Vulpian has, according to his own account, set himself to examine the results announced by others, and while pursuing this examination with the sincere love of truth, it has been his task to often refute the most seductive systems. The subject he has chosen is one of the most interesting to the medical profession. As a matter of fact the principal function of the vaso-motor nerves is to regulate the distribution of nutritive fluids among the tissues. When these nerves are stimulated, the vessels to which they are supplied contract, and by this means the blood which flows from the surface of a wound can be diminished or even stopped. Under the contrary condition, the vessels become dilated, the hæmorrhage is more considerable, and the venous character of the blood is less marked throughout the tissues. It would undoubtedly be very useful for a surgeon to be able at his will to excite or paralyse the vaso-motor nerves, and thus change the conditions of the circulation in any desired part of the body. By this means he could at pleasure remove hæmorrhagic congestions and fluxions; he would have unlimited control over the nutritive changes, so as to increase them at one point and lessen them in another.

It has been asserted that direct and continuous electric currents, differing in this respect from induced and interrupted currents, may afford this twofold power of dilating or contracting the vessels according to the direction in which the current is made to travel. This theory has been brought forward most especially by the late M. Legros. M. Vulpian's researches, however, have led to a diametrically opposite result. He affirms that the different kinds of current act in the same, or nearly the same manner, on the vaso-motor nerves. According to the researches of MM. Legros and Onimus, when a galvanic current is passed along a nerve containing vaso-motor fibres, the ascending currents, that is to say, those currents in which the negative pole is placed near the centre, and the positive pole near the periphery, cause contraction of the vessels; whereas the descending currents, or those where the position of the poles is the reverse of the preceding, cause dilatation. The experiments, however, on the web of the frog's foot, which were repeated with M. Carville under the most favourable conditions, were not attended by the expected results. When the

lumbar nerves of a frog were electrified, the continuous currents either produced in the web of the foot the same results as the interrupted current, only less marked, or they had no effect whatever. The descending currents appeared never to produce any vascular dilatation. In M. Vulpian's experiments, these currents induced contraction of the vessels with more certainty than did the inverse currents.

As to the experiments in which MM. Legros and Onimus passed continuous currents through the skin and the subjacent parts, it is evident, M. Vulpian says, that they cannot be greatly depended on to prove that a current of one kind acts on the vaso-motor nerves and makes the vessels contract, whilst currents of another kind acting on these same nerves produce dilatation of the same vessels. Not only is there no warrant for believing that the nerves are thus acted upon, but it is clear that all the tissues included in the course of the current are excited, those of the skin among others; and that this excitation of the tissues may provoke reflex dilatation of the vessels, which greatly complicates the result. In order to demonstrate that the currents thus employed directly produce dilatation or contraction in any part of the body through the medium of the vaso-motor nerves, it would be necessary to previously separate these nerves from the nerve-centres, or else to cut all the excito-motor fibres of that region, so as to prevent any intervention of reflex vascular action.

Thus it is impossible to dilate the vessels by the direct action of continuous currents on the vaso-motor nerves. Whatever may be the direction of the current, whether from the periphery to the centre or from the centre to the periphery, from the moment the currents operate, always supposing they are applied to the nerve itself, they produce excitement and cause the vessels to contract, in the same way as they would under the influence of an induced and interrupted current.

As to the secondary and indirect dilatations of these vessels, their mechanism is as yet very imperfectly understood. They have been included in the category of reflex action; but very little is known at present as to the way in which they are produced. Whether they are active or passive is a controverted question.

Indeed, reflex actions, as they are understood at the present time, are of many different kinds. They include the different influences which pass from nerve to nerve, which were formerly called sympathetic actions, automatic movements, the active phenomena of animal life, etc.

The word reflex has been adopted to represent the hypothesis of a nervous current reflecting itself on a central point, like the refraction of a ray of light on a mirror, and, so to speak, following an angle of incidence which determines its direction. In this hypothesis, a nervous wave once reaching the centre by a nerve-filament may by repercussion depart by another, and reach a more or less near or distant organ. Reflex action exists when this wave has been transmitted by a sensory nerve, and returns in the track of a motor nerve. This is the simplest of all cases, and one that has been especially studied by M. Claude Bernard. The explanation of these phenomena seems to be thoroughly satisfactory, being in accordance with the most elementary notions of physiology and mechanics.

When sensory and motor filaments are united in a part of their course so as to constitute one and the same nerve, originating at the same level from

the same centre, and reaching the same region of the periphery, it is easy to understand how they form a nerve-pair, along which a fluid resembling electricity can be transmitted from end to end. This is, in fact, explained by the laws which preside over the movements of inanimate bodies. The conception becomes more complex if we imagine a sensory action which takes a longer course across the centre, and, finding itself in the company of several motor nerves, chooses, as though by an elective preference, one path rather than another.

This idea becomes still more complicated when phenomena which may be explained by a kind of mechanical repercussion, or a purely physical transmission of the nervous wave, terminate in correlated action; as happens, for instance, when frogs and ducks cry out and jump from reflex action after they are decapitated.

After all, however, this is not where the difficulty lies. The signification of the word *reflex*, used with reference to movement, is always intelligible. The expression 'reflex neuralgia,' however, is also admitted, which signifies the action of one sensitive nerve on another. This is an instance of what our predecessors called sympathy; and the change of terms does not seem to throw much light on the subject. In fact, it is no longer a question of nerve-fibre. We must in the first instance suppose that the current of a sensory nerve can, in some instances, take a different course from the one which it takes generally; and that from centripetal it can become centrifugal. This current, starting from the periphery, and passing along a sensory nerve, having reached the nervous centres, instead of remaining there, or passing on to a motor nerve, even though the way is clear, chooses another sensitive nerve. Here it is reflected afresh, either in the course of its journey by the influence of other currents proceeding from the periphery, which come into collision with it, or else at the extremity of the nerve, where it cannot stop, but takes another direction, terminating the second time in the nerve-centre.

If we admit that this explanation is intelligible we cannot say that it is simple, and much less so when it is a question of the succeeding class, that of reflex paralysis.

Reflex paralysis is a somewhat contradictory term, for it is certain that it cannot be intended to describe a state of inaction, or a negative action which can itself be reflected. It is the *reflection* of an action which produces this inaction. If the explanation of reflex neuralgia, given above, be accepted, it is easy to understand that two currents moving at the same time in opposite directions along a nerve, may be arrested by the influence they exercise on each other, and that a paralysis of sensation may be the result.

E. LAWSON.

PELLIZZARI, TOMMASI, PERRONCITO, LEWIS,
COBBOLD AND GIACOMINI ON CYSTICERCI.

(Continued from page 642.)

Before proceeding to give a definitive answer to Perroncito's question respecting the causes of the frequency of tapeworm in Italy, it may be as well to refer to the recent *brochure* by Dr. Giacomini.* This author appears to have had no opportunity of perus-

ing Pellizzari's communication already cited, and consequently it is not surprising that he should, in common with others, have accepted the conclusions of Perroncito. The respective contributions of these authors were probably made public about the same date. Be that as it may, Giacomini clearly perceives that, whatever precautions of a hygienic character are suitable for the prevention of disease arising out of the consumption of measly pork, the same, or at all events similar, measures ought to be adopted with the view of checking tapeworm affections arising from the ingestion of other kinds of meat, especially veal and beef. Like Pellizzari, he is satisfied as to the human origin of the small bladder-worms found in cattle, and establishes this position not only from the oft-quoted experiments of Leuckart and Mosler, but also from those conducted by Cobbold and Simonds in England, and by Professor F. Saint-Cyr in France. From a careful review and consideration of all the facts of the case, he recommends a more complete supervision (*una sorveglianza maggiore*) over the flesh of oxen before it is employed commercially, and greater precaution when employing veal as food, by causing it to be subjected to a high temperature, in order that the parasites may be killed before it is ingested. It is evident that Giacomini thinks that a temperature exceeding that of boiling-point is necessary for the destruction of the beef and veal measles, since he immediately adds: 'Though experiments have not been made with the object of ascertaining the amount of resistance of heat which the unarmed cysticercus can bear, yet, judging by those conducted by Professor Perroncito on the measles of the hog, we are in a position to say that a temperature of 135° Cent. (275° Fahr.) is necessary for the destruction of an isolated cysticercus, whilst the heat should be raised from 150° to 200° Cent. (302° to 392° Fahr.) for ten or fifteen minutes, in order to ensure the complete destruction of the cysticerci encapsuled in the interior of a piece of meat.' We have freely translated and abridged this portion of Giacomini's text, because his statements are pretty much the same as those we have already quoted from Perroncito, as cited by Tommasi. But, in the next place, Dr. Giacomini must permit us to say that he is in error, quite unintentionally no doubt, when he states that experiments have not been performed on the cysticerci of the ox. So far from this being the case, our Italian friends must be told that, valuable as are the results they have obtained in this connection, similar experiments on temperature were long previously conducted by our countryman, Dr. Lewis; and these researches had quite as much to do with the measles or cysticerci of beef as they had with those of the hog, if not more. Naturally but, few foreign investigators can have had access to the work in which Lewis's experiments were originally recorded, and to which therefore we are in duty bound to call their attention.* Thus, also, Tommasi, whose excellent translation of Cobbold's *Manual* does him much credit, has fallen into the error of supposing that the investigations of Lewis were made in England; although, from the text of some portions of his own edition of that work, it might have been inferred that the researches were made in India. It is of very little moment where the experiments were carried on,

* Sul *Cysticercus cellulosæ hominis* e sulla *Tænia medio-canellata*, contributo allo studio dei Cestoidi Parassiti dell' Uomo; del Dott. Carlo Giacomini. Torino; 1874.

* 'A Report on the Bladder-Worms found in Beef and Pork.' By T. R. Lewis, M.B. [Being Appendix B, in the 'Eighth Annual Report of the Sanitary Commissioner with the Government of India.' Calcutta; 1872.]

but Tommasi's statement (appendix, *loc. cit.* p. 161), wherein he says that Pellizzari's experiments, in which he himself took part (*ai quali io stesso ho assistito*), are even more complete than those made in England by Dr. Lewis, and in Germany by Dr. Küchenmeister, cannot be allowed to pass unchallenged. If Tommasi had enjoyed the opportunity of consulting Lewis's original memoir, we feel sure, from his evident candour, that he would not in any measure have under-estimated the extent of our countryman's labours. The memoir by Lewis is singularly complete, also of great length, and well-nigh exhausts all the facts that can have any interest in relation to the question of public health as affected by parasitically diseased meats, especially those of beef and pork. Towards the close of his essay he expressly states, as the result of investigation: (1) 'That exposure to a temperature of 120° Fahr. for five minutes will not destroy life in cysticerci, but that they may continue to manifest indications of life for at least two or three days after such exposure; (2) That exposure to a temperature of 125° Fahr. for five minutes does not kill them; but (3) after being subjected to a temperature of 130° Fahr., for five minutes, they may be considered to have perished. After exposure to this and higher temperatures, in no instance have I been able (he adds) to satisfy myself that the slightest movements took place in their substance when examined even under a high power. At least, it may be confidently asserted that, after exposure for five minutes to a temperature of 135° to 140° Fahr., life in these parasites may be considered as absolutely extinct' (p. 139). Thus we find the explicit statements of Lewis and Pellizzari in perfect accord; and seeing that their conclusions are alike the result of very careful and independent inquiry, conducted, moreover, with equal skill, it only remains for us, so far as this particular phase of the subject is concerned, to say that the question at issue is finally solved. These investigations make it perfectly clear that cysticerci of all kinds, whether found in veal, beef, or pork, cannot retain their vitality when exposed to a temperature of 60° Centigrade, or, in other words, 140° Fahr.

Having disposed of the prime question relating to the sanitary importance of the study of the cysticerci, it yet remains for us to refer to other points of scarcely less practical significance. In the first place, there is the subsidiary question raised by Perroncito as to the causes still operating to render tapeworms almost endemically prevalent in certain countries, even in those where so many admirable hygienic measures are known to be in full operation. Again, however, we must so far trespass on our reader's patience as to defer our remarks on this head to a future number, at the same time adding that many other interesting particulars, more or less intimately associated with the life-history and distribution of the cysticerci, yet remain to be discussed.

(To be continued.)

TRICHINOSIS has lately caused fifty-two deaths at Linden, near Hanover—thirty-four in males, and eighteen in females.

THE GERMAN CHOLERA CONFERENCE in Berlin held its concluding meeting on October 20. The proceedings are in the hands of Professors von Pettenkofer and Hirsch, for arrangement and publication.

ON THE TREATMENT BY MINERAL WATERS OF CHRONIC DISEASES, AND ON THE PRINCIPAL SOURCES ADAPTED TO THE VARIOUS MORBID CONDITIONS. BY M. GUBLER.*

(Continued from page 676.)

VI. Affections of the Genito-urinary Organs.

I shall commence with the affections common to both sexes, vesical catarrh, blennorrhœa in man and leucorrhœa in woman. The first thing is, to treat by appropriate waters the general condition of the system on which they depend, as chlorosis or anæmia, scrofula, dartre, or syphilis; but local treatment is also required.

Topical injections with the aid of the ordinary irrigator, or better with Wickham's speculum, are employed: 1. To clear the surfaces; 2. To soothe the remains of inflammation; 3. To astringe the tissues; 4. To neutralise the acidity of the urethro-vaginal pus; 5. To destroy the lower organisms which breed in the secretions. The first indication can be obtained with any water, the next with any tepid soft indifferent water. Astringency is obtained from the sulphate of iron and alum waters. The common lime and alkaline waters act as absorbents. The bituminous sulphurous waters, and those which contain alkaline sulphites and hyposulphites, in short, those which are termed degenerated sulphur waters, I conceive to have a special antizymotic action on the secretions.

Thus, Ussat and Pougues, which are used for leucorrhœa, are strong calcareous waters; Remollon, Saint-Alban, and Saint-Nectaire might render similar service, being rich in lime; while the alkalinity of the Vichy waters accounts for their successful use in uterine complaints. Many feeble degenerated sulphur waters are much employed, as Saint-Sauveur, Eaux Chaudes, Moltig, and Olette. One may recommend on the same ground La Preste, Aix, and Luchon. But the sulpho-bituminous waters of Euzet and Saint-Boès are still more efficacious in leucorrhœas, kept up by the darts habit. Sterility, a condition common to both sexes, may depend on various very different anatomical conditions. In the male, aspermia from cryptorchidia, from absence of or from injury of the testicles, the retention of the semen by obliteration of the different canals, or spermatorrhœa with its disastrous consequences, may be the cause. In the female, the absence of ovules, the congenital absence of ovaries, or temporary sterility caused by polysarcia, or an obstacle to the passage of the germs from the ovaries, or an obstacle to their meeting the fecundating fluid, caused by catarrh of the neck of the uterus, are the commonest causes. It is evident, that no one method of treatment can suit all these varied conditions; yet every station, in Germany in particular, has a *Bubenquelle*, which renders ladies fertile. The fact is, a young woman every now and then becomes a mother, after the use of a course of mineral waters. Are we, like Trousseau, to attribute this mainly to change of life, or to consider it a matter of chance? I reckon it unfair not to give the waters credit for a power of removing some causes of sterility. Male impotence and pollutions can be treated successfully by hydrotherapy, sea-bathing, tonic and restorative waters of any sort. Good

* *Journal de Thérapeutique*, no 10 et seq.

results have been got at Lamalou, at Bourbonne, in the Pyrenees, and in Auvergne. In the opposite sex, the return to fecundity may be the result of the natural treatment of obesity, of anæmia, of want of innervation, of the removal of obstacles which opposed themselves to the maturation of the ova, or to their impregnation. How many wives have become mothers after sea-bathing, or courses of steel-waters, or after having some mucous obstruction of the neck or of the cavity of the uterus, removed by sea or salt or sulphurous waters! We know already what waters suit best most of these conditions, including catarrh of the genital organs; but we have still something to say on amenorrhœa, dysmenorrhœa, chronic metritis, and periuterine engorgements.

Torpid amenorrhœa requires the waters suitable for the chlorotic and the anæmic, steel, sulphur, chloride of sodium, simple and complex, and especially the latter, when they contain iron. I may cite Spa, Forges, Gréoulx, Luchon, Vic sur Cère, Chateaufort, Saint-Nectaire, etc., and I must not forget Saint-Moritz, which owes much to its elevation.

Dysmenorrhœa, when painful, membranous, or even menorrhagic, when of congestive origin, with or without general plethoric condition, requires entirely different remedies. I should recommend Vals with its strong baths, and the internal use of some of its weaker alkaline waters, or baths at Vichy, with the internal use of small quantities of the waters. Or a bath of indifferent water of moderate temperature may answer quite well, as Aix en Provence, Bagnères de Bigorre, Bagnoles de l'Orne, Ussat, or indifferent waters of a higher temperature, as Plombières, Bains, Luxeuil, Dax, Nèris.

For all menorrhagias, including passive ones, we prescribe restorative iron waters, and especially the sulphated and mixed sulphated, the Source Galtier at Cransac, Dominique and Saint-Louis at Vals, Auteuil, and Passy.

In chronic metritis, the general condition of the patient is sometimes more important than the local lesion, and it may be better to endeavour to get up the general condition, rather than to operate directly on the uterine congestion. Thus one would order, according to the case, steel waters, gaseous or non-gaseous, or containing all the neutral salts of the serum, and also bear in view any strumous, any dartrous, or syphilitic taint. Only one must select waters that are not very stimulant, and the topical application of which could be easily borne.

Scrofulous patients may be sent to Balaruc, Lamotte, Bourbon l'Archambault, Bourbon Lancy, or to Saint-Nectaire, where there are douches of carbonic acid, as at Couzan and Saint-Alban, and sometimes to sulphur-waters, but best of all, to those of Gréoulx, which contain a considerable amount of chloride of sodium and a notable proportion of sodium and bromine.

The waters of Gréoulx also answer, when there is any cutaneous affection. If in such cases there be also a tendency to any local or general inflammatory action, then the mild sulphur-waters of Eaux Chaudes (Source de l'Esqurette), Saint-Sauveur, and especially the more alkaline waters of the Eastern Pyrenees, Moltig, Olette, La Preste, are to be preferred.

When there are any indications of gout, we may prescribe the alkaline waters, but if there be no special complication, we may content ourselves with such harmless waters as those of Dax, Evaux, Nèris, Plombières, and others.

[Here, too, M. Gubler ignores entirely all the German iron waters, also the Austrian ones of Marienbad and Franzensbad, of much service in uterine congestions, and the systematic treatment at such salt-baths as Kreuznach, Nauheim, and others. France is perfectly well off for indifferent and for sulphur waters, and has admirable establishments at Plombières, Nèris, Bagnères de Bigorre, Cauterêts and Luchon. I should say, that the sulphated waters can find but a very limited application, just as the waters of Sandrock in the Isle of Wight are entirely forgotten. We in England scarcely understand what darte and herpetism are,—a sort of diathesis always in the mind of Frenchmen.—Tr.]

VII. *The Treatment of Neuropathies.*

The affections of the sensitive motor system to be now mentioned, occur usually among young women, and are chiefly treated at the stations for uterine affections. I mean painful or spasmodic affections of moderate violence, which usually are classed under the name of hysterical. This condition is almost always connected with general debility, loss of tone, anæmia, and chlorosis. Our first object therefore ought to be, to improve the general health and strength of the patients, by food, climate, exercise, hydrotherapy, sea-bathing, saline waters, iron waters, and those at once iron and saline. But sometimes these remedies cannot be borne by irritable constitutions, and then we must have recourse to more soothing measures.

Painful neuroses and neuralgias, gastric, hepatic, uterine or vesical, and spasmodic neuroses; also slight tic, palpitation, spasm of the œsophagus, cramps of stomach, or of the uterus, dysuria, and other manifestations of the disordered nervous system, are to be met by the sedative action of the tepid slightly-mineralised waters—Moltig, with its Bain des Délices, Saint-Sauveur, Eaux-Chaudes, Nèris, Encausse, Ussat, Bagnères de Bigorre. In such cases we make use of very prolonged baths. The internal use of such feebly mineralised waters is entirely secondary.

VIII. *Treatment of Affections of the Digestive Canal.*

Painful dyspepsia seems to require carbonated waters, such as those of Couzan or Saint-Alban, to soothe it. Nevertheless, as gastralgia is sometimes the consequence of irritation of the mucous membrane of the stomach, or the expression of a diathesis, other waters may be employed with advantage. There are, on the one side, absorbent antacid alkaline ones, as Vals and Vichy, and carbonated lime ones, as Saint-Alban, Alet, Rémollon, etc.; on the other hand, the waters used in the thermal cure of rheumatism, such as those of Plombières, and the very hot waters. Atonic dyspepsia, with its indigestion, pyrosis, and flatulence, is often the result of general weakness and anæmia. Sometimes a restorative course of iron waters will be the best means of restoring the digestion. But on the whole, carbonated waters, with a large supply of carbonic acid, with bicarbonate of soda, and neutral salts, such as Le Cayla, Spa (?) Prugnes, Vic sur Cère, Saint-Nectaire, etc. Gastric acidity and flatulence, the ordinary results of bad digestion, do not require any special waters. But they may be kept under by the use of absorbents and warm local applications, or by avoiding the use of too gaseous drinks.

Dyspepsia, connected with the lithic acid diathesis, is best combated with the alkaline waters of Vals and Noyrac, which have establishments, or at home by those of Marcols. The waters of Royat, Rouzat, and Saint-Nectaire, are equally suitable, on account of the presence of carbonate of soda and of lithia.

Rheumatic dyspepsia can be well treated at Plombières, Bains, Luxeuil, Chaudes Aigues, Dax, Aix-les-Bains, and at other stations with very hot waters: dartsous dyspepsia by arsenical and sulphur waters. The varied mineralisation of Sylvanès adapts it for such cases.

Irritative dyspepsia, amounting at times almost to gastritis, requires the weaker alkaline waters of Vals, those of Soultzmat, the lime ones, containing little gas, of Alet, Foncirque, Rémollon, or the indifferent ones of Bagnoles (Orne), or of Evian, or Amphion. Waters rendered emollient by the quantity of organic matter which they contain, will have the same effect, such as the Source Hôpital at Vichy, or Moltig in the Eastern Pyrenees.

Catarrhal dyspepsia is to be treated by weak aperient waters at Brides, Plan-de-Phazy, or at Andabre, Chatel Guyon, Saint-Gervais, etc., unless it depends on some specific diathesis, which it might be necessary to modify in the first instance.

Affections of the intestines that may be treated with mineral waters, are habitual constipation, neuralgia of the bowels, and chronic diarrhœa. Habitual constipation is usually relieved by the aperient waters which I have just enumerated, but the results are seldom permanent. Sometimes a more permanent cure may follow a stimulant or tonic course of iron, or chloride of sodium waters.

Enteralgia only yields to the external application of the very hot waters, without reference to their mineralisation.

The same class of waters may be used for chronic diarrhœa—as the rationale of their treatment is, to derive from the bowels to the surface, by the use of very hot waters. At their head comes Plombières, and after it Bagnères de Bigorre, Bains, Bourbon Lancy, Luxeuil, Ussat, and several others.

If the diarrhœa be kept up by a general condition, such as hydræmia, too small a supply of blood-corpuscles, too much albumen in the blood, with or without albuminuria, then we must have recourse to the warm saline iron waters, in order to enrich the serum and diminish the tendency to serous exhalations. Carlsbad enjoys a high repute in such cases; nevertheless Saint-Nectaire, already often mentioned, is superior to it in varied mineralisation, and is not so purgative. After it I place Saint-Maurice, Chateaufort, and lower, on account of the absence of carbonate of soda, Chatel Guyon. When there are intestinal ulcerations, we must have recourse to detersive and cicatrising waters, containing sulphur and iodine. The sulphur waters of La Preste, Olette, Moltig, no doubt would produce good effects. The especially silicated spring Mauhourat at Cauterêts, appears destined to be of good service in chronic irritation of the mucous membrane of the intestines, and in the sequelæ of dysentery. It ought to be the same with the waters of Challes—but Gréoulx ought to be superior to all waters in repairing ulcerations of the intestines.

[A good water for chronic diarrhœa is certainly a desideratum. Plombières has put forward pretty strong evidence of its efficacy. I do not see why our own Bath should not be better than many of the

foreign earthy waters. The waters of the Mauhourat at Cauterêts have been successful in curing enteralgia, but it is a question whether their trifling amount of silicates has anything to do with this. Challes and Gréoulx, particularly the first, are remarkable waters, but we have no evidence of their being used in diarrhœa. It is fair to expect a good deal from Saint-Nectaire, without going the length of seeing how it supplies the blood with all the elements it wants. My impression is, that in this section M. Gubler describes rather results that have been hoped for, than obtained.—Tr.]

IX. *Treatment of Affections of the Liver.*

Many morbid conditions of the liver are ameliorated or cured by the use of mineral waters; for instance, biliary concretions and hepatic colics, the chronic inflammations of the liver, which are so common in tropical lands, the varied changes of the organ, such as the ordinary enlargement of the gland, retention of bile, stasis of blood, hyperplasia of the connective tissue, the effects of old inflammations or even suppurations, all going under the name of liver-cakes or Indian livers, but of far more varied nature than simple hypertrophy.

Two great baths, Carlsbad and Vichy, have almost a monopoly of liver-cases. In reality, they are not both suited for the same forms of disease, and each should have special cases selected for it. The interests of the two great rival baths are not irreconcilable, and it ought to be possible to select cases suited for strong alkaline waters, and others for the more complex alkaline waters, containing some chloride of sodium and sulphate of soda. The following are my views on the subject. Suppose a woman with a tendency to biliary concretions, fat and belonging to a gouty family, who has already had some pain in her liver, with a suspicion of jaundice, with urine for the time containing bile, but otherwise in fair health, the strong alkaline waters of Vichy or of Vals answer for such a case.

On the contrary, if there be obstruction of the gall-ducts, and the patient have already had repeated attacks of hepatic colic and jaundice, or if there be any permanent retention of bile, with enlarged liver, and with failure of general health, then I prefer Carlsbad, or one of the mixed waters in the centre of France, Saint-Nectaire, Saint-Maurice, Saint-Myon, etc. Saint-Nectaire would be equivalent to Carlsbad, if its waters only contained a little more sulphate of soda, and were thus more distinctly aperient; and this defect is easily remedied by adding a little magnesia, or a glass of bitter water, or of the *eau verte* of Montmirail.

To tell the truth, if we only wanted simple cathartic and dialytic effects, we might be contented with passing a season at Brides, Chatel Guyon, or Santenay, and going to drink afterwards at Vals or Vichy. I have frequently recommended this. But there is something special in the complex elements of the waters of Saint-Nectaire and of Carlsbad, which makes them indispensable for patients who have reached the stage of cachexy, and are already weak and anæmic, and who require restorative as well as resolutive waters. As to chronic enlargements of the liver, which are only developed as a consequence of dysenteric ulceration, or of intermittent fevers, they require the carbonate of soda and chloride of sodium waters, more than strong alkaline ones, on account of the grave disturbance of the general health.

Slightly purgative effects may be got from some of

the strong chloride of sodium waters, such as those of Balaruc or Bourbonne, or from the dissolving action of some weak alkaline waters. La Preste, in the Eastern Pyrenees, has a great name in such cases, and is resorted to by all our marine officers, to reduce the enlarged livers they have contracted in Senegal or in Cochinchina. The alkalo-ferruginous source of Boulou and of Marcols might be used in like manner, but only the first of the two has an establishment.

If, however, the patient be very feeble, and it be considered sufficient to dilute the secretions in general, and the bile in particular, some of the indifferent waters will do, as Evian, or some a little more mineralised, as Contréville, Vittel, Martigny, and Prugnes.

If we have to do with a primary hepatalgia or a neuralgia of the liver, where there is only a suspicion of biliary concretions, then a high temperature is to be sought in the waters of Plombières, Bains, Bagnoles, Rennes, etc., applied exteriorly in stimulant baths, and in revulsive douches.

[There is here no mention of Marienbad, though not German, any more than Carlsbad, nor of the Swiss Tarasp, both valuable in engorgements of the liver. Under this head, too, and that of dyspepsia, Kissingen, Homburg, Wiesbaden, and a host of springs, have been omitted. The successful action of the hot but feebly mineralised springs of La Preste on tropical livers, deserves further investigation. There is a parallel in the case of Weilbach and Nenndorf, cold sulphur-springs, but somewhat more highly mineralised than La Preste. M. Gubler has done what no German could do; he has discussed affections of the digestive canal and of the liver, without referring to abdominal plethora, or to hæmorrhoidal congestion.—*Tr.*]

J. MACPHERSON, M.D.

(To be continued.)

ANATOMY AND PHYSIOLOGY.

WEGNER ON THE NORMAL AND PATHOLOGICAL GROWTH OF THE LONG BONES.—In the *Archiv für Pathologische Anatomie und Physiologie*, part i. 1874, Wegner defends the theories of John Hunter, Duhamel, Flourens, and others, from the attacks of Dr. J. Wolff. The first question which Dr. Wegner discusses is, Is there or is there not, in the developed tissue, an interstitial growth? He remarks that it must be well understood that the question refers exclusively to the fully formed osseous tissue. No one has directly even observed such an interstitial growth. Ruge's endeavours to demonstrate such a process by the aid of the microscope, merely show that the osseous corpuscles differ somewhat as regards size and distance from each other, at different periods, but do not prove interstitial processes in the formed osseous tissue. A great difficulty in applying the apposition theory to the growth of the lower jaw, arose from the circumstance that too little weight was attached to Hunter's postulated absorption upon the surface of the bones, and because nothing was seen of the processes of resorption. At present we know, from Lieberkühn's experiments with madder, that at the anterior edge of the coronoid process a continual resorption takes place in the growing animal, which is strikingly proved by Humphry's ingenious experiments (*Transactions of the Cambridge Philosophical Society*, vol. xiv).

Wegner found that the bones of dogs and rabbits fed for some time on phosphorus are best adapted for the purpose. The process of external resorption is best seen on the posterior surface of the lower end of the femur, where, in the rabbit, a resorption-surface is seen occupying the whole circumference immediately above the condyles.

Wegner repeated the well-known experiments of J. Hunter on eighty animals—dogs, rabbits, cats and fowls. Dogs and cats are less adapted for this purpose, as suppuration usually supervenes after the operation, and also because the osseous substance in young individuals is too soft to hold the nails. The first series of experiments consisted in driving, at measured distances, several nails into the middle portion of the diaphysis of the tibia or femur, in such a manner that their surface was at the same level as that of the bone. After some months, the animals were killed and the intervals between the nails again measured, when in not one instance had the intervals changed in a measurable degree. In some few instances, in fowls, the distance had increased, but it had also diminished in some, owing no doubt to pathological changes.

The whole series of arguments advanced as indirectly supporting the theory of interstitial growth were to refute at the same time the apposition theory. Dr. Wegner thinks that an interstitial expansion of the developed osseous tissue does not take place, but that the absorption-processes are everywhere visible and demonstrable; that the change in the form of the lower jaw, the shifting of the bony projections, etc., are pathological formations (exostoses and pararticular callus); and finally, that the stability of the architecture of the bones is perfectly compatible with the apposition theory. Nothing can be indirectly advanced against it, and in favour of it the proofs are many and positive.

All the experiments, says the author, tend to show that the growth in length of the cylindrical bones proceeds from the epiphysal ends. In harmony with this are the results of feeding with phosphorus. Whilst during the feeding with madder the last deposited layer appears red at the intermediary cartilage, it becomes dense and compact during the feeding with phosphorus, instead of spongy; and if the phosphorus be omitted for a certain time, there immediately appears at the intermediate disc a layer of common spongy substance. If now the phosphorus feeding be recommenced, alternate layers of spongy and compact tissue will be found. Pathological observations also support the apposition and resorption theories; e.g., the interrupted growth after premature synostosis of the cranial sutures, etc. Dr. Wegner concludes a long paper, which is only the first part of his intended communication, by affirming that his numerous experiments bear out to the fullest extent the observations of all authors except Dr. Wolff, to the effect that the growth of long bones is effected by way of apposition and resorption, and that the interstitial interpretation of Dr. Wolff is entirely erroneous. H. A. REEVES.

ONIMUS ON THE EFFECT OF ELECTRICITY ON THE SPAWN OF THE FROG.—M. Onimus, in a recent communication to the Société de Biologie, of Paris, states that by electrifying the eggs of the frog, the development of those which are in connection with the negative pole will be accelerated, whilst the hatching of those in connection with the positive pole will be either retarded or stopped.

PATHOLOGY.

TROISIER ON PULMONARY LYMPHANGITIS.—In a pamphlet on 'Pulmonary Lymphangitis,' Dr. Émile Troisier gives an account of the minute anatomy of the lymphatic vessels of the lungs, and mentions the results of several experiments made by him, proving the connection between the cavity of the pleura and these vessels. He then explains the reason why he applies the term lymphangitis to the disorders of the lungs which he has under consideration. The word lymphangitis does not only indicate those lesions of the lymphatic vessels which are strictly speaking inflammatory, but includes those which proceed from other irritating causes.

The consideration of the disease is divided in two parts. In the first, cancerous lymphangitis is considered; in the second, the other forms of the lesion are enumerated and lightly touched upon.

The main part of the work consists of a description of cancerous lymphangitis (*lymphangite cancéreuse*). This disease presents two distinct varieties, their differences depending mainly on the position which they occupy in the lung.

Superficial or pleural lymphangitis, as its name indicates, attacks the lymphatic vessels situated on the surface of the lung. This form is generally dependent on the presence of cancer in the walls of the chest. It presents the appearance of certain star-shaped nodules, deposited apparently on the pleura, and sending off processes which intersect each other, and at the point of intersection are slightly enlarged. These processes are the lymphatic vessels. The nodules are essentially cancerous; the processes themselves are not so distinctly specific. On section, they exhibit canals lined with layers of large cells, their centres filled with a caseous magma.

Pleuro-pulmonary lymphangitis, the second variety of cancerous lymphangitis, attacks not only the superficial but also the deep lymphatics of the lung, the pulmonary and bronchial glands. Dr. Troisier relates two cases of this disease, giving the *post mortem* appearances observed, with the results of the microscopical examinations of the lymphatics. The symptoms by which these two varieties may be known are not very definite. They are common to cancerous infiltration, œdema of the lung, congestion, and bronchitis. The symptoms which seem to present somewhat of a distinctive characteristic appearance are cyanosis and dyspœa.

In the second part of his work the author enumerates the other forms of the lymphangitis, which are not cancerous. They are adenomatous, tuberculous, simple, and purulent lymphangitis.

Adenomatous Lymphangitis.—The existence of this form of the lesion seems, according to the author, to be at present doubtful. He, however, quotes two cases which go some way to prove that the disease may exist. It would seem from these two cases to be a condition of the lymphatic vessels dependent on a swollen and somewhat inflamed state of the glands.

Tuberculous Lymphangitis is rare. It consists of a prolongation into the lymphatic vessels of the tuberculous matter derived from a mass of that deposit. The propagation of the material by the lymphatic vessels seems to cause the formation of fresh tuberculous centres on their walls.

Simple Lymphangitis is best seen in pleurisy,

when a section is made through the layer of exudation and the subjacent serous membrane. The lymphatics are found to be distended with material, similar to that of the exudation on the pleural surface. It is probable that there is a true inflammation transmitted to the lymphatic vessels, at the time that absorption of the exudation begins to take place.

Purulent Lymphangitis is secondary to suppuration, either of the pleura or of the lungs. It is not a simple matter of absorption of pus-cells, but there is no doubt that the lymphatics themselves participate in the inflammatory action.

The facts brought forward by the author, in support of the theory of the connection between the pleural cavity and the pulmonary lymphatics, seems to be conclusive. The pathological results of his researches are also of value, as lending additional weight to the arguments in favour of the transmission of cancer by the lymphatic vessels.

W. KESTEVEN, JUN.

SURGERY.

BATTEY ON A SAFE AND READY METHOD OF RELIEVING INTESTINAL OBSTRUCTIONS.—The method advocated by Dr. Robert Battey (*Atlanta Medical and Surgical Journal*, June, 1874) is the use of distensile enemata of a much greater volume than has heretofore been practised. The author refers to the recent statements of Gustav Simon, Milbrand, and others, that by placing a patient upon the knees and elbows, so that the anus becomes the highest point of the intestinal canal, from five to nine pints of liquid could be introduced into the intestines before the sphincter yielded. These facts, the author asserts, are neither new nor remarkable; and he claims for himself priority in having proved in a paper written by him, and published in August, 1871, that much larger quantities of fluid can be injected into the gut with perfect safety and great advantage in cases of obstructed intestine.

Dr. Battey thus describes his method. Water of the warmth of blood is the best fluid, of which at least four gallons should be ready for use. The patient should lie on the left side. The syringe should be strong, durable, and continuous in its action. When complaint of distension is made, the injection should be suspended a little until the feeling of tenesmus passes off; then it may be resumed slowly and gently, while the patient is encouraged to retain it as long as possible. An assistant should firmly press with both his hands a folded napkin over the anus, around the tube, so as to assist the power of retention; when the combined efforts of the patient and the assistant will no longer prevent the escape of fluid, the syringe should be worked rapidly and forcibly for a few moments until the distress of the patient peremptorily demands cessation; then, and not until then, should he be allowed to get up. Dr. Battey adds this valuable caution: the full power of the distensile enema is never to be evoked *late* in a case of obstruction, or when there is reason to apprehend from symptoms, or the length of time it has existed, that the walls of the intestinal tube have been materially weakened by resulting inflammation, or that gangrene has commenced.

In December, 1871, the author published a series

of cases he had treated. In the second case, a boy aged twelve received about twelve pints of liquid into the bowels, with prompt relief to a serious intestinal obstruction supposed to be intussusception. In another case, a man aged fifty-five received nearly twenty-four pints also with prompt relief. In the other cases the quantity of liquid employed was not so accurately estimated, but it may be safely asserted that from twelve to fifteen pints were used in each case. An anodyne was always administered some time before the injection.

The experience Dr. Battey had accumulated induced him to conclude, when his paper was published in 1871, that water could be passed *per anum* not only into the rectum and colon, but on through the ileo-cæcal valve into the small intestines; but subsequently an accidental observation suggested the inquiry, Can the distensile enema be carried through the entire intestinal tract into the stomach and out of the mouth of the living subject? The author relates two cases in which, he believes, this actually occurred. In the first, a woman, aged twenty-three, suffered from supposed obstruction; into her intestine soapy liquid was persistently and slowly thrown, the abdomen being the while gently kneaded, until, when from eighteen to twenty pints had been introduced, copious vomiting of fluid occurred and the patient declared that she tasted the soapy water. In the second case, a man, aged sixty, suffering from symptoms of strangulated or incarcerated hernia, was chloroformed, and tepid water was injected into the rectum until such copious vomiting of discoloured fluid took place, as to convince those present that the water had passed through the stomach. This patient was cured of his obstruction. In January last, Dr. Battey and Professor J. T. Johnson experimented on the cadaver, so that the progress of the fluid upwards through the alimentary canal might be watched by the eye. The following is Dr. Battey's account of the experiment. The room was cold, the temperature being below 40°; the abdominal contents and the water employed for injection so cold as to numb the hands. Notwithstanding these disadvantages, the liquid passed readily along the entire length of the colon, and found no obstacle at the ileo-cæcal valve to its onward progress. Upon reaching the upper portion of the smaller intestine, greater difficulty was encountered on account of the collapsed and matted condition of the cold cadaveric mass; movement of the convolutions, however, by the hand, permitted the fluid to pass still onwards, until it finally reached the stomach, and even flowed out of the mouth on to the table. Further on in the paper, the author proceeds to discuss the varied forms of obstruction to which distensile enemata, aided by anodynes and anæsthetics, are applicable. He considers there is no variety in which, if not too long delayed, much benefit may not be obtained. As to the mode of action, he is of opinion that the distension of the intestine below the obstruction exerts a tractile power on the gut, at the same time that the upward force of the water will push before it an intussusception, or a knuckle of intestine from its imprisonment. It will soften and disintegrate faecal accumulations; and recent adhesions and bands may be stretched or ruptured in the safest possible manner. Dr. Battey avers that the proposition successfully carried out of introducing into the alimentary canal so large a quantity as two and a half or even three gallons of fluid with safety, he believes to be new and original with himself; but, however this may be, the success-

ful passage of fluid throughout the entire tract from anus to mouth, in either the living or dead body, he claims as unique and unprecedented. He much prefers the injection of water to air, the latter being, in his opinion, an irritant to the intestine, setting up by itself spasms and colicky pains; he also very strongly objects to distension brought about by the injection successively of an alkaline and an acid liquid, as generating an uncontrollable force likely to rupture the intestine; he admits that the intestine might be ruptured by water if a pump of adequate power be used, but says there is no danger to be apprehended with an ordinary elastic-bulb syringe, and further that the peril in which a patient is who is suffering from intestinal obstruction justifies some little risk in the method of treatment.

Dr. Battey considers the long flexible O'Beirne's tube as quite unnecessary, and concludes by protesting against the general injunction, 'that injections are not to be pushed beyond the point at which they are borne without much suffering; and also against the statement that they will very rarely succeed after the invaginated portion of the intestine has become swollen by congestion, and the peritoneal surfaces in contact have become adherent.' On the contrary, he thinks that even in apparently hopeless cases many lives may be saved by a perseverance in the use of copious distensile injections.

W. ALLINGHAM.

WALB ON REUNION OF INTEGUMENT AND CARTILAGE DETACHED FROM THE NOSE BY A RAPIER STROKE.—In this case, communicated at a recent meeting of the Niederrheinische Gesellschaft (reported in *Berliner Klinische Wochenschrift*, no. 36, 1874) some minutes elapsed between the injury and the application of the detached portion of nose, since this could not at first be readily found, and had to be cleansed from adherent dirt. This portion had been cut off from the left ala, and consisted at some parts only of skin, and at others of the more superficial layers of the cartilage. At no part of the raw surface thus left on the nose was there an opening into the cavity of the nostrils. The flap was divided by a transverse wound into two halves, which only just hung together. This was well fixed to the nose by seven peripheral sutures, and by a needle and looped suture at its central part. The subsequent treatment consisted in the continuous application of moist and warm dressings. The flap, which at first was pale, gained in the course of two hours a dark-blue colour, except at some parts at its margin, and over a large island in its centre, where the looped suture had been placed. These parts, however, soon acquired the pink hue of flesh, and retained their vitality. The sutures were removed on the third and fourth days, and healing was perfected without suppuration. The fact that the suture applied to the centre of the flap in this case suggested to the author the advisability of a similar proceeding in the transplantation of large pieces of skin. In conclusion, the author stated that small pieces of skin taken from amputated limbs had often been applied by him with successful results to granulating wounds after an interval of twenty-four hours.

VOLKMANN ON THE TREATMENT OF HYGROMATA CONTAINING FALSE CARTILAGES.—At the recent congress of the German Society of Surgery (proceedings reported in *Berliner Klinische Wochenschrift*, no. 35, 1874) Professor Volkmann stated the results of

his experience as to the use of drainage in cases of hygroma with floating contents. In three cases of this kind treated in the preceeding twelve months, an incision three-quarters of an inch in length was made into the sac at its upper, and another similar incision at its lower extremity; the free contents of the sac were then extruded, and the bodies adherent to its inner surface rubbed off by pulling backwards and forwards through the cavity a tightly stretched drainage-tube. This tube was then left in the sac, and the seat of the operation covered by Lister's dressing. In all three cases obliteration of the sac resulted, without any intercurrent disturbance or the slightest local reaction. He did not observe phlegmon, diffused suppuration, or necrosis of tendon, and the mobility of the fingers remained unimpaired. The removed floating cartilages were found to be concretions formed of coagulated albuminates, and were not organised growths. The name, therefore, of hygroma proliferum is not well adapted to these growths. In one case, where a portion of the cyst-wall was excised and examined, the inner surface was found to be coated by a thick layer of coagulum, which was rough and studded by tufts projecting into the cavity of the hygroma. Volkmann has also observed along the threads of a seton introduced into an hygroma a thick layer of coagulated albuminates, and at the free extremities of the thread firm club-shaped appendages of the same material.

GERSUNY ON A CASE OF FIBROMA OF THE ABDOMEN.—The author reports (*Wiener Medizinische Wochenschrift*, no. 36, 1874), a case of a large fibromatous tumour, growing from the anterior wall of the abdomen, and projecting into the abdominal cavity. An operation was performed by Professor Billroth for the removal of this growth, and the patient recovered. On account of the great size and excessive vascularity of the tumour, and of the extent of peritoneum removed in the operation, the case seems to be of special interest. The patient was a woman, aged twenty-four years, who had had three children, the last six months before the operation. About two years and a half previously, she noticed for the first time a hard round tumour near the anterior and superior spine of the ilium on the right side. After it had been present for a year and a half, and when the patient consulted Professor Billroth for the first time, the growth was of the size of a man's fist, and seemed to be prolonged into the cavity of the abdomen. As it then caused no trouble and seemed stationary, it was thought advisable not to interfere. After the subsequent confinement, however, the tumour increased rapidly in size, gave trouble on account of its weight, and was the seat of severe pains radiating along the right leg. Professor Billroth was again consulted, and again thought it well not to recommend an operation, on account of the danger of excessive hæmorrhage, and of wounding a large portion of peritoneum. On May 24, 1874, the patient again applied to Professor Billroth, who then decided, at her request, to operate for the removal of the rapidly increasing growth. At this time the woman was pale and seemed delicate; the right half of the abdomen was occupied by a prominent round tumour of the size of a man's head, which extended above to the lower margin of the thorax, externally to a line drawn directly downwards from the anterior axillary fold, and internally to a vertical line drawn

two inches to the left side of the linea alba.¹ The integument was much stretched over this growth, and marked by large venous convolutions. Part of the growth was situated immediately under the integument, and part of it extended deeply into the abdomen. Its surface was smooth, and its consistency very hard. There was slight mobility from below upwards, and from side to side. There was no œdema of the right lower extremity, and the pulsation of the right femoral artery could be distinctly made out.

The patient having been put under the influence of chloroform, an incision was made through the skin along the course of the linea alba from the umbilicus to the pubic symphysis. From the middle of this, a second incision was made obliquely to the right, over the most prominent portion of the tumour. The much stretched anterior layer of the sheath of the rectus abdominis muscle having been divided, the surface of the tumour was exposed, and the rectus muscle was found to be in a state of fatty degeneration, and pushed over to the right side. During this stage of the operation there was much hæmorrhage from the dilated veins of the integument and those on the surface of the growth. The posterior layer of the sheath of the rectus muscle was found to be enclosed within the tumour, and had evidently been the original seat of the disease. A considerable portion of the posterior surface of the tumour was next found to be closely adherent to the peritoneum, and wounding of this membrane in further steps of the operation could not be avoided. As the patient, on account of the continuous venous hæmorrhage, was manifestly in a state of collapse, the operation was completed as rapidly as possible; the portion of peritoneum in firm adhesion to the tumour being excised, and the connection of the morbid mass with the broad muscles of the abdomen divided with quick strokes of the knife. Corresponding to the excised portion of peritoneum, which was as large as the hand, could be seen the omentum completely covering the intestines. The bleeding during this last stage of the operation was still very profuse, and proceeded mainly from large veins. The ragged portions of the anterior sheath of the rectus muscle having been cut away, the vertical wound was closed, the sutures being applied separately to the peritoneum and the skin above, and carried through all the layers of the abdominal wall below. The peritoneum formed a large loose sac on the right side of the wound, through which sac two drainage-tubes were passed from above downwards, so that their ends projected at the upper and lower extremities of the line of incision. The transverse wound was then closed by sutures, and a third drainage-tube inserted at its outer extremity. The operation was followed by extreme collapse, which was treated by the administration of black coffee and wine, and by bandaging of the lower extremities from the toes upwards, in order to drive the blood to the central organs. The patient slowly recovered from this condition, and in the evening had a good pulse. The further progress of the case was satisfactory, and on July 9 the patient was sent home cured, and with the abdominal wound quite healed. The only bad symptoms, presented during the course of the after-treatment were some few attacks of febrile disturbance, dependent on diffuse suppuration between the layers of the abdominal wall, and retention at first of wound-secretion, and subsequently of pus.

W. JOHNSON SMITH.

DEMARQUAY ON FOREIGN BODIES IN THE ŒSOPHAGUS.—At the meeting of the Société de Chirurgie de Paris on October 14, M. Demarquay communicated particulars of two cases in which children had swallowed coins. In the first case, M. Demarquay immediately detected the presence of a foreign body in the œsophagus, and performed œsophagotomy. He ascertained that the coin had perforated the œsophagus and had fixed itself in the perforation, whence it was easily extracted. The child died, however, and at the necropsy M. Demarquay found a retro-œsophageal abscess which had discharged itself into the right pleural cavity. In the case of the second child, who had also, according to his own account, swallowed a coin, neither M. Demarquay nor MM. Denonvilliers and Nélaton, who assisted him, could feel any obstruction. The latter surgeons hoped that the intruder had ended by finding its way into the stomach, and had been expelled in the natural way. But after some time violent symptoms of chest-disease made their appearance, and, the child having died, a purulent collection was found in the right pleural cavity. It was evident that the origin of this collection had been a retro-œsophageal abscess produced by the foreign body, which had opened into the pleura. Struck by these facts, M. Demarquay instituted some experiments on animals, particularly dogs, by introducing into and fixing different kinds of foreign bodies in their œsophagus. When, after some time, the animal was killed, M. Demarquay invariably found a retro-œsophageal abscess opening into the right pleural cavity. This identity of results in men and animals is very remarkable; and M. Demarquay came to the conclusion that, in consequence of the rapidity with which foreign bodies produce ulceration and perforation of the wall of the œsophagus, they must never be allowed to remain in that canal, and that it is desirable to perform œsophagotomy very quickly.

BASCHIERI ON A CASE OF GUNSHOT WOUND OF THE BLADDER.—Dr. A. Baschieri describes in the *Bulletino delle Scienze Mediche* for August, 1874, the case of a lad named Andrea Morelli, aged sixteen, who was shot through the abdomen, the muzzle of the gun being at the time in contact with the part. He ran about a hundred yards, holding his hands to his belly, and then fell.

The hypogastrium was blackened, and in its lower right fourth was a circular hole, leading nearly perpendicularly into the pelvis, and giving exit to a continuous flow of urine. At the upper part of the aperture, which was at a distance of about two and a half inches from the umbilicus, there was an elevation, resistant to the touch, containing the charge (or a portion of it); this was removed by an incision through the sheath of the right rectus abdominis.

To facilitate the escape of urine, Dr. Baschieri made an incision downwards for more than a centimètre, and had the patient placed on his right side. Pieces of sponge were ordered to be applied to the wound to absorb the urine; and to be frequently renewed, and not reapplied until they had been well washed in a solution of carbolic acid. Charpie was laid over the sponge, and over this a bladder of ice. Ice was also given by mouth, and an opiate mixture was prescribed, to relieve the occasional attacks of pain in the abdomen. In the evening, a catheter was introduced; the operation gave great pain, but no urine escaped. Some warm water which was injected

through the catheter escaped entirely through the wound, turbid with charcoal *débris*.

At the end of four days, the fever having become very severe, sulphate of quinine was prescribed. For the ice, cold-water dressing was substituted; and this was in turn replaced by linseed-meal poultices, which were continued until the contused tissues were thrown off, leaving a large zone covered with healthy suppurating granulations.

On the thirteenth day, while the patient was at stool, urine escaped by the urethra; and from this time it continued to come by the natural passage.

The patient had a febrile attack, ushered in with severe rigor; it was arrested by sulphate of quinine. One day, the flow of urine was impeded by an obstruction in the urethra; and, on this being overcome, thirty lead shots were found at the bottom of the vessel. Others, making in all one hundred and forty, were expelled at various times. The patient had completely recovered two months after the accident.

Dr. Baschieri believes that the charge of the gun entered the bladder as a single projectile, and that it then became scattered, the shot becoming embedded in the mucous membrane, from which they were detached by a process of suppuration, which was the source of the febrile attacks.

GRANDESSO-SILVESTRI ON AMPUTATION OF THE HUMERUS BY ELASTIC LIGATURE.—In no. 30 (1874) of the *Gazzetta Medica Italiana Provincie Venete*, Dr. Grandesso-Silvestri describes the case of a man, aged thirty, the subject of caries of several ribs and of the left elbow-joint, in whom threatening symptoms of pyæmic poisoning appeared. The elbow being the seat of severe and obstinate pain, Dr. Grandesso-Silvestri considered that amputation was indicated; but, as it was evident that the patient could not bear the loss of blood, he decided on using the elastic ligature. An India-rubber thread surrounded with linen thread, having a diameter of about two twenty-fifths of an inch, was passed twenty times round the arm, below the insertion of the deltoid. The patient, who had taken nearly two drachms of chloral hydrate, felt the application of the cord, but did not give any signs of pain. Dr. Grandesso-Silvestri calculated that the cord acted with an equal pressure of twenty-one kilogrammes (about 46½ pounds).

The next day, the patient was free from fever, and had a good appetite. The limb immediately below the ligature was dead. Grandesso-Silvestri then removed the forearm, and took away from the arm half of the soft tissues remaining under the ligature. On the sixteenth day, the ligature had reached the bone; on the thirty-ninth day, the bone was loose; and on the fortieth day, it fell off with the ligature. The stump was cicatrised posteriorly; but on the anterior part had a dirty aspect, and the end of the bone protruded nearly an inch. During the process of detachment, there was rather severe pain. The wound was dressed with calomel powder and dry charpie; the stump became clean; and when the case was described, healing was nearly complete, and the bone had ceased to protrude.

Dr. Grandesso-Silvestri believes that the process might be shortened by cutting through the bone when the soft parts have been divided by the ligature; but he prefers waiting for the bone to fall off of itself, as in this way it is divided more smoothly.

In giving an abstract of the case in the *Gazzetta*

delle Cliniche for September 22, Dr. Daniele Baidardi remarks that all surgeons allow that an operative procedure is the more to be recommended if it be simple of performance. In this respect, Dr. Grandesso-Silvestri's plan is no doubt superior to every other. It gives greater security against hæmorrhage than the galvanic cautery, especially when the artificial production of local anæmia is not employed. The operation, however, has the drawback of being slow, and of keeping a diseased part long under the patient's observation. In the case related, there was severe pain during the prolonged action of the elastic cord. Grandesso-Silvestri did not have recourse to the 'bloodless method,' fearing that noxious principles would be carried into the circulation, and increase the danger of the patient; but it will occur to every one that he might have applied an elastic tube (as has been done by other surgeons), and completed the operation without hæmorrhage in a very short time, and with less trouble.

A. HENRY, M.D.

MATERIA MEDICA AND THERAPEUTICS.

JACOBI ON INFANT DIET.—Dr. A. Jacobi, Clinical Professor of Diseases of Children in the College of Physicians and Surgeons, New York, writes as follows on the important subject of the diet of infants.

Of the Nursing Infant.—A much more frequent occurrence (than the increase in the normal percentage of salts) is too large a percentage of casein in mothers' milk. . . Casein will be curdled in hard masses, or will pass into the intestines in the same condition, and be evacuated almost unchanged, or covered, perhaps, with bile, a little viscid mucus, sometimes, even, with a streak of blood. . . The indications are either preventive or curative. The increase of casein is frequently accompanied by a diminution of sugar, and the neutrality may be replaced by a faint acidity; and the effect is constipation. . . I remove it (the constipation) in many instances by simply adding a moderate amount of sugar to the normal food. . . One or two scruples of loaf-sugar are dissolved in one or two teaspoonfuls or more of tepid water, and given to the baby just before nursing. . . The next indication is, to prevent the too sudden effect of the gastric juice upon the surplus casein, and keep it from coagulating in hard masses. . . Instead of the sugar-water mentioned above, I give the baby each time before it is put to the breast, a tablespoonful or more, according to age, of strained and well-sweetened oatmeal, for reasons, and prepared in a manner, I shall designate hereafter. . . For this plan, also, which has been serviceable in many cases where the former simple one would not suffice, I claim good theoretical reasons, and the result of various, and, I believe, unbiased observation of a long number of years. . . The third indication is curative, and refers to the correction of the excess of acid of any origin that may exist in the digestive organs. . . The main concomitant symptoms of acidity are either constipation or diarrhoea, the principal alkalis in question, preparations of potassa, soda, lime or magnesia. . . Wherever neutralisation is required in a case of constipation, we should resort to magnesia, soda, or potassa; whenever we have to deal with a diarrhoea, carbonate of magnesia would be indicated. Whenever no de-

cided indication was to be followed, we might select either of soda or potassa, the bicarbonate or the carbonate; the latter, however, when given in large doses, is too ponderous and less digestible than the former.

Artificial feeding cannot be successful without milk. . . . Where the choice is given, therefore, cow's milk ought to be preferred. . . There is in cow's milk less sugar, less of free alkali, less butter, but more and more coagulable, casein. . . Practically, when a relative deficiency of sugar in cow's milk is to be supplied, loaf sugar always answers the purpose. . . It is advisable to add an alkaline salt (the carbonate or bicarbonate of potassa or soda) to the cow's milk, and best at once when the milk is put aside for the infant's use. . . Thus I add one or two grains of either of the salts to every meal of the new-born, besides a small quantity of common salt—chloride of sodium—and a larger dose in proportion to age. . . Cow's milk ought to be cooked at once, in order to keep it as long as possible from turning sour, and ought to be preserved in a cool place, if not in an ice-box. . . Next in order, is the question how to prevent the great coagulability of the casein of cow's milk; I add, instead of water, a substance, which, by its physical consistency and cohesion, is apt to hold milk in suspension. Thus I mix quite thin and transparent mucilage with (boiled and skimmed) milk, and add the desirable quantity of sugar and salt, or soda. . . Looking for a substance which, while fulfilling that object, is absolutely indifferent, from a chemical and physiological point of view, it is gum arabic. . . An indifferent substance of this sort may be all that is desired for very young infants. . . The selection of articles of food, which are, at the same time, of a mucilaginous consistency, and nutrient, is perhaps, not so difficult as it appears to be. . . Barley and oat-meal are the two substances that I mostly employ. . . A teaspoonful of either is boiled in from three to six ounces of water with some salt [a pinch] for twelve to fifteen minutes, the decoction to be quite thin for very young infants, thicker for later months, and then strained through a linen cloth. Infants of four to six months are to have equal parts of this decoction, which ought to be made fresh for every meal; and (boiled and skimmed) cow's milk and sugar is to be added. . . The desire of parents to procure the milk of one special cow for their infants, I believe to be based upon a mistake. . . I have always advised the plan of giving the average milk of a farm, and have never been sorry for the results, in all parts of the city.

General Rules.—1. *Nursing Babies.*—Over-feeding does more harm than anything else. Nurse a baby of a month or two every two or three hours.

Nurse a baby of six months and over, five times in twenty-four hours, and no more. When a baby gets thirsty in the meantime, give it a drink of water. No sugar. In hot weather (but in the hottest days only), mix a few drops of whisky with either water or food, the whisky not to exceed a teaspoonful in twenty-four hours.

2. *Feeding Babies.*—Boil a teaspoonful of powdered barley (grind it in a coffee-grinder) and a gill of water, with a little (a pinch) salt, for fifteen minutes, strain it, and mix it with half as much boiled milk, and a lump of white (loaf) sugar. Give it luke-warm through a nursing bottle.

Keep bottle and mouth-piece in a bowl of water when not in use.

Babies of five or six months : half barley-water and half boiled milk, with salt and white sugar. Older babies, more milk in proportion.

When babies are very costive, use oatmeal instead of barley. [Add from three to six grains of bicarbonate of soda to each evening meal, for a few nights.] Cook and strain.

When your breast-milk is half enough, change off between breast-milk and food.

In hot summer weather, try the food with a small strip of blue litmus paper. If the blue paper turns red, either make a fresh mess, or add a small pinch of baking-soda to the food.

Babies of ten or twelve months may have a crust of bread and a piece of raw beef to suck.

No child under two years ought to eat at your table. Give no candies; in fact, nothing that is not contained in these rules, without the doctor's order.

Summer Complaint.—It comes from over-feeding, and hot and foul air; never from teething. Keep doors and windows open. Wash your children with cool water at least twice a day, and oftener in the very hot season.

When babies vomit and purge, give nothing to eat or drink for four or six hours, but all the fresh air you can. After that time you give a few drops of whiskey in a teaspoonful of ice-water every ten minutes, but not more until the doctor comes. When there is vomiting and purging, give no milk.

Give no laudanum, no paregoric, no soothing syrup, no teas.

DALKIEWICZ, MALLEY, AND OTHERS ON THE TREATMENT OF GOUT AND URIC ACID GRAVEL BY THE FERRO-BENZOATE OF LITHIA.—Several works lately published on gout and uric gravel (*Progrès Médical*, July 20), contain interesting information on the therapeutic employment of the benzoate of iron and lithia in gout and gravel. Some of the writers, as Dr. Dalkiewicz in his *Généralités sur la Goutte et son Traitement*, 1873; and Dr. Malley in his *Considérations Générales sur les Dyspepsies, la Gravelle et la Goutte*, recommend the simultaneous employment of the *eau de Vittel*, and of M. Trehyou's benzoate of iron and lithia. Benzoic acid when ingested changes into hippuric acid at the expense of the proteic matters, the principal source of uric acid. Hippuric acid forms very soluble salts in conjunction with the ordinary bases (soda, potash, and ammonia) of the fluids contained in the organism, whilst the urates of these same salts are insoluble in the fluids of the animal economy, since from them are formed calculi and gravel. Starting from these data, M. Gubler has given the preference to the employment of benzoic acid. (Gubler, *Commentaires du Codex Medicamentarius*.) But this acid cannot long be used by itself, as experiments made in the Paris hospitals have proved.

M. Trehyou has therefore wisely thought it useful to associate the benzoic acid with lithia, a very soluble product, which prevents a fresh production of uric acid, and forms with that already existing an urate of lithine, the most soluble of all the urates. However, the benzoate of lithia has its drawbacks in the long run, like all the alkalines; and with the object of lessening them as much as possible, M. Trehyou conceived the idea of adding iron to it.

Dr. Michel, and Dr. Clément in his '*Traitement de Gravelle urique avec de nouvelles Expériences sur l'Action des Alcalins*', show that M. Trehyou has not been mistaken in this method; an opinion corroborated

by M. Folle Desjardins in his *Essai sur les divers Traitements de la Goutte normale*, by MM. Palanchon, Drs. Raimondi, Maurel, Mallet, Lescure, etc. The summarised observations of cases in these works contain sufficient warrant to encourage medical practitioners in employing M. Trehyou's benzoate of iron and lithia in gout and uric acid gravel.

BARTHOLOW ON DEEP INJECTION OF CHLOROFORM FOR THE RELIEF OF TIC DOULOUREUX.—Dr. Roberts Bartholow communicates to *The Practitioner* (June 1874) an account of several cases of this painful affection treated successfully by hypodermic injections of chloroform. The infra-orbital branch of the nerve was the seat of the tic in the cases reported; and Dr. Bartholow's operation consisted in passing the needle under the upper lip in the direction of and near to the infra-orbital foramen, and then injecting from ten to twenty minims of pure chloroform. Considerable pain at first ensues, followed by a feeling of numbness and anaesthesia of the parts into which the chloroform diffuses. A puffy swelling quickly forms at the site of the injection, and an induration which lasts for several days follows. One very severe case operated upon in this manner gained relief from one injection covering a period of months.

WENZEL ON ICED CLYSTERS IN DYSENTERY.—Dr. Wenzel (*Annales de la Société de Médecine d'Anvers*, and *L'Indépendente*, April 1874) having had occasion to treat a great number of cases of dysentery, has found the best remedy to consist in the injection of ice-water into the rectum. The first case he treated in this way was one of severe dysentery. There were intense fever, abdominal pains, excruciating tenesmus, and profuse sanguineous evacuations. To check the hæmorrhage, injections of ice-water were ordered every two hours, which not only caused the sanguineous evacuations to cease, but also removed the tenesmus, enteric pains, and fever. The beneficial effect of these injections was so evident that the patient urgently demanded their repetition whenever the pains threatened to reappear. Dr. Wenzel considers this treatment more satisfactory than any other in acute cases, although in chronic cases it can only be expected to afford temporary relief.

FORMULARIES.

COD-LIVER OIL EMULSION.—The *Archives of Electrology and Neurology*, for May 1874 (quoted in the *Ohio Clinic*), gives the following formula as one that suits better than any other :—Cod-liver oil, ʒiv ; Glyconin, ʒix . Glyconin is made by thoroughly triturating glycerine and yolk of egg, equal parts. Add to the glyconin thirty drops of the essential oil of bitter almonds; then add the oil to the glyconin very slowly, drop by drop, stirring vigorously all the time. The success of the emulsion depends on the thoroughness with which this task is performed. Then add Jamaica rum, ʒij ; Dilute phosphoric acid, ʒss to ʒj . The average dose is one tablespoonful after meals, being regulated mainly by the phosphoric acid.

If properly prepared, the medicine does not separate, keeps for a long time, and is rather agreeable to the taste. If need be, pyrophosphate of iron can be added, or strychnine, or Fowler's Solution. It has been used especially in hysteria and allied affections, and in organic diseases of the nervous system it is

also valuable. Consumptives take it in preference to cod-liver oil. As cod-liver oil has a somewhat unpalatable name it is sometimes better, in prescribing for nervous patients, to call this the phosphoric emulsion. The fishy odour cannot be entirely neutralised; but for those who are not familiar with cod-liver oil, neither the odour nor taste of this emulsion, when well made, suggests the presence of oil.

INHALATIONS IN ASTHMA.—Ætheris sulph., 30 parts; Acidi benzoici, 15 parts; Balsami Peruviani, 8 parts; or, according to another formula, Ætheris sulph., 2 parts; Spiritus terebinthinae, 15 parts; Acidi benzoici, 15 parts; Balsami Peruviani, 8 parts. Place the mixture in a vessel having a large opening; the warmth of the hand is sufficient to volatilise the materials, and inhalations may be used four or more times a day as occasion demands.

AURAL SURGERY.

WEBER-LIEL ON PROGRESSIVE DEAFNESS.*—The present teaching of the character and recognition of the chief affections of the ear is in little conformity with the actual facts. Almost all cases of deafness accompanied by subjective noises are referred to chronic affections of the middle ear. This is so far true; but all affections of the middle ear are not of a simple catarrhal inflammatory nature. Many more varied, primary, and secondary pathological processes are met with, which implicate not only the mucous membrane of the middle ear, but also the other structures of that cavity, viz., the muscles, joints of the ossicles, vessels (vaso-motor paralyses), and particularly the nerves supplying these, and the nerves in connection with them. Cases described as catarrhal are often clearly of a rheumatic nature, of which Hippocrates and other old writers made observation.

The chronic affections of the ear may be divided into two great groups: 1. Those in which tinnitus is not present, or only by complications, or during intercurrent inflammations; and, 2. Those in which tinnitus is present from the beginning, and forms a constant and afflicting symptom. The first class has not a strong tendency to progress. The diseases included in it—as, for example, the chronic purulent catarrh of the middle ear—may exist for years without any increase of the deafness. The second class is characterised by the more or less progressive character of the diseases comprehended in it.

Of the progressive ear-affections spoken of formerly as the 'nervous,' latterly as the 'chronic dry catarrh of the middle ear,' a large number are characterised by disturbances of the equilibrium of and diseases in the muscular apparatus of the middle ear, though it must be allowed that these are also frequently caused by disturbances of innervation from catarrhal changes. The sensitive apparatus of the middle ear must be looked at as a system of counterstraining and antagonistic forces, whose relations to each other may be affected at any one point by motor, sensitive, or trophic influences, or by mechanical causes; these, by rendering the normal capabilities of motion difficult, alter the

function of the whole apparatus, and give different expressions of disease according to the importance of the part specially affected. One of the affections described belonging to this group, whose presence, either complicated or uncomplicated, is very common, has its true and lasting causes in primary or secondary mobility defects of the muscular apparatus of the Eustachian tube. In it the paralysis of the tensor veli plays a chief part for two reasons. 1. There arises from the paralysis of the tensor veli collapse of the tube, and therefore hindrance of the proper continual ventilation of the tympanic cavity. 2. Allowing, from Weber-Liel's newly given observations, that the tensor veli acts as an antagonist to the tensor tympani, when the elastic strain and contractility of the tensor veli is entirely or partially paralysed, not only collapse of the tube occurs, but an antagonistic contraction of the tensor tympani also; and so, the want of air in the tympanic cavity being added to the effect of the anomalous straining of the powerful system of active factors in the mechanism of the tympanic cavity, a high degree of nutritive and functional anomaly in the cavity and labyrinth must in time be occasioned. Thus arise, according to Weber-Liel, many cases of catarrh of the middle ear, from the hyperæmia *ex vacuo*, caused by the rarefaction of the intratympanic air, and the retardation of the tympanic and intratympanic circulation by the increased amount of strain and limited motion of the structures from the abnormally contracted tensor tympani. This simultaneous defect of air in the cavity and contraction of the tensor tympanic cause, (1) an abnormally strong tension of the tympanic membrane, (2) an abnormally tight fixation of the chain of ossicles, and (3) an increase of the intralabyrinthine pressure, since the stapes is pressed into the labyrinth by the ossicular chain. Thus the reception and conduction of the vibrations and the vibrating capability of the implicated portions are much prejudiced. As the functional expressions of these disturbances, arise subjective auditory sensations, and also frequently sensations of faintness. At the beginning of the affection disturbances of hearing may be present, but they are not then noticed as deafness, but rather as acoustic hyperæsthesia for certain noises; and gradually thereafter defects in the capability of hearing, especially during mixed conversation, make their appearance, and again are followed by symptoms which are spoken of as accommodative disturbances; and now, when the other ear begins to suffer, the tinnitus gradually arises and increases. The collapse of the tube and the abnormal contraction of the tensor tympani continuing, there develop in time secondary changes in the sound-conveying apparatus, the hyperæmia of the tympanic cavity already present often increasing through the passage of catarrhal conditions from the pharynx to the now easily affected parts, and intratympanic exudations are easily produced by slight attacks of cold. The structures in the tympanic cavity being, on account of the defect of air in the cavity, approximated to each other, give these exudations points for adhesive attachments. A not necessary but very frequent consequence of the continual impressing and fast fixing of the stapes in the fenestra ovalis is a synostosis of the stapes, and other anomalies in the joints of the ossicles; the local hyperæmia, which is especially marked in individuals of the gouty, rheumatic, and syphilitic diatheses, playing an important part in the production of such changes. In time

* On the Character and Curability of the most frequent form of Progressive Deafness; with investigations and observations. By Dr. Fr. E. Weber-Liel (F. E. Weber), Teacher of Aural Surgery in the Berlin University. Augt. Hirschwald: Berlin, 1873.

the hyperæmia of the tympanic cavity lessens, the 'Stauungs-hyperemie' leads to interstitial connective tissue growth and wasting of the vessels, and trophic changes of different kinds are seen, atrophy of the tympanic membrane being common. It is comprehensible that in time changes in the circulation and nutrition of the labyrinth must also occur, not only on account of the continual and increasing pressure from the cavity, but on account of the difficulties under which the conducting apparatus must act. It is a matter of observation that such patients at the beginning of a conversation often hear moderately well, but when the affected ear has been strained for an hour or so they complain of giddiness and increased tinnitus, which symptoms can only be referred to an increased flow of blood to the labyrinth. If the patient labour from some pulmonary or other affection which retards the return of blood from the head, the connection of the arachnoidal space with the labyrinth through the ductus cochleæ, a connection more fully shown by Weber-Liel in the *Monatschrift für Ohrenheilkunde* for 1868, explains why such symptoms appear markedly in such patients. A course of Carlsbad waters sometimes alleviate the symptoms of such patients, but the ear-affection itself continues. Vaso-motor paralysis may also complicate the affection.

In one chapter a copious delineation of all the symptoms is given as they are seen in the best marked cases. There is one series of symptoms explained which till now has received little or no attention, viz. the snapping noises which are heard by the patient during the motions of chewing and swallowing, and which are common in the first stage of the affection, seldom later. The moist walls of the Eustachian tube lie, on account of the relaxation of the tensor veli, on each other; but in swallowing the muscle is yet in a condition to separate the walls from each other, and thereby arises the snapping noise. The proof of the correctness of this explanation is given by the effect of the intratubular electrification of the muscular apparatus of the tube, which sometimes succeeds in abolishing the noise, making the tube pervious to a weak air-douche, lessening the tinnitus, and removing aside the already beginning deafness.

Weber-Liel holds that ear-affections seldom depend on pharyngeal catarrh, which, he says, is much more often present without any aural affection than the latter without the former. With the condition above described, he says, there is nearly always a pharyngeal affection present, but this will be seen by an examination of the pharynx to be of a catarrhal nature in about one half of the cases only. The patient complains of a scratching in the throat and of a feeling of drawing together, or as if a hair lay upon the pharyngeal mucous membrane, which inclines him to hawk or cough, this latter feeling being especially noticed when the patient is thirsty. When he speaks for some time, frequent hawking becomes imperative, and speaking becomes difficult, and tires him easily. Singing the higher notes cannot be easily accomplished, and the patient becomes quickly hoarse. Certain acts of swallowing can no longer be made with the necessary energy, and they quite refuse, for example, by Politzer's method, the opening action in the Eustachian tube. Weber-Liel interprets such appearances as neuroses. The continued use of the tympanic catheter, or the passage of bougies through the tube, and the employment of his method of intratubular electrification of the muscular apparatus of the tube have convinced the

author that in cases where an imperviousness of the tube to the air-douche has been diagnosed, this seldom results from a catarrhal swelling of the tube, but from a collapse of the tube-walls, through the abolition of the counterstraining force of the antagonistic muscles. The air-douche does not pass through, but the introduction of the bougie is easy. This conspicuous non-concurrence of the results of the tactile and acoustic examinations, combined with the appearances of *post mortem* examinations, confirm the supposition of a collapse of the tube.

Weber-Liel is not satisfied with the statements hitherto given out as to the anatomical and physiological relations of the moving factors of the Eustachian tube and tympanic cavity, and has therefore himself made numerous investigations, and gives out some new and important facts. He makes special note of the fact, that the muscular apparatus of the tube exerts not only a dynamic action upon the structures with which it stands in connection, but also has a static power, whereby the elastic tension of the non-contracted muscles must have a continuous influence upon the elastic tissues connected with them. From this point of view the question arises whether there is, apart from the act of swallowing, a continuous interchange of air in the tympanic cavity through the Eustachian tube. Weber-Liel holds the proof by no means conclusive that the tensor veli contracts at the moment of swallowing, and so opens the tube; he thinks that the tube may be caused to gape at that moment by the pulling downwards of the palatopharyngeal muscles on the pharyngeal fascia, into which the end fibres of the tensor veli reach, and through these pull upon the cartilaginous attachment of the muscle, and so cause the gaping of the tube.

A seemingly important discovery of Weber-Liel's is that the pterygoideus internus is not only a muscle of mastication, but that it also contracts the fascia of the tube. He thinks that this explains a series of symptoms which have been hitherto inexplicable. When, for example, the pterygoideus internus is energetically contracted, a powerful straining is felt in the ear (in the membrane of the tympanum), and a singing noise is heard in the ear of that side. This, he says, is brought about by the fact that, the tensor tympani having an origin from the fascia of the tube, and being covered in its whole length by a continuation of the same, a stretching of it will cause a tension of the muscle, and consequently a straining on the membrane of the tympanum must be the consequence. The giddiness and tinnitus sometimes experienced by patients suffering from aural affections is also, he considers, explained by this action of the pterygoideus internus, through the fascia, on an already abnormally retracted tensor tympani. The investigations which he made on the anatomy of the tensor tympani itself support, he believes, this theory. He finds that the muscle does not arise from fixed but from movable points, from the cartilage of the tube and the fascia covering it, so that every change of tension of these parts, and especially of the hook of cartilage, from which the strongest bundle of fibres originates, causes a change of tension of the tensor tympani, and of the structures of the tympanic cavity attached to it. Since the hook of tube-cartilage is moved chiefly by the tensor veli, Weber-Liel has designated it the antagonist of the tensor tympani, and of this antagonistic action he brings further proof. He has determined that the result of pulling on the muscles from both sides goes through a fixed point, the hamulus ptery-

goideus and the rostrum cochleare. He says that the statement till now received that the tendon of the tensor tympani winds round the rostrum is a mistake, and asserts that it is fixed in the depth of the band of the rostrum cochleare. He devotes a chapter to the analysis of the above-mentioned symptoms, and their explanation by anatomical and physiological observations.

In the chapter on etiology he speaks of the causes which contribute to relaxation, insufficient action, and paralysis of the muscles in question. General weakly conditions from disease, parturition, excessive exertion, unhealthy conditions of life, will have disturbing influences on muscles already weak, and this is often the case with the muscular apparatus of the tube. He thinks that the muscles of the tube of the left side participate in the general more feeble development of that side, and thinks that the affection nearly always begins on the left side. Chronic catarrh of the mucous membrane covering the muscles appears to have often been the starting-point of defective functional ability of this group of muscles. In nervous individuals, in those much affected by grief or care, with different nervous lesions (*e.g.*, of the trigeminus), the innervation of this portion is very easily disturbed under disposing influences. Rheumatism, tubercle, typhus, diphtheritis, progressive muscular atrophy, chlorosis, and anæmia are all mentioned as causes. He concludes this chapter with a series of *post mortem* examinations, which go to corroborate the opinions above given.

The therapeutics have the disadvantages of different treatment at different stages. In the first stage, the sole indication is to bring the ventilation of the Eustachian tube into the normal force, and to remove the relaxation or paresis of the muscular apparatus of the tube, especially that of the tensor veli, on the disappearance of which will also disappear the antagonistic contraction of the tensor tympani. The intratubal electrification of the muscles of the tube is the chief means. The striking results which are often obtained by this prove, according to Weber-Liel, that the character of the affection is such as he has described. In later stages, the treatment must be directed against the secondary changes, after the appearance of which only very imperfect results are obtained. The only remedy which then assists is the restoration of a persistent opening in the tympanic membrane, and tenotomy of the tensor tympani.

At the close of the treatise there is a series of cases given, illustrating the diagnosis and treatment; and several well-executed engravings are added for the better explanation of the author's anatomical investigations.

By all interested in aural surgery, this monogram ought to be perused with care. The new facts there given out must assist greatly in the elucidation of one of the probably most common, and at the same time most intractable, diseases which surgeons have been called upon to treat.

W. LAIDLAW PURVES.

NEW INVENTIONS.

THE 'PEN' VACCINATOR.

Dr. R. Harvey Hilliard has had an ingenious little instrument, bearing this name, made for him by Messrs. Maw, Son, and Thompson, of Aldersgate Street. It is made like a drawing-pen, such as accompanies sets of mathematical instruments, and presents several advantages over most other contrivances for the same purpose.

Its points are sharp enough to abrade or scratch the cuticle, without drawing blood, a very great advantage in more ways than one. They are made of a hard incorrodible metal, and when not in use, shut tight into the portable case, which thus constitutes a 'moist chamber.' There is room enough between the blades for lymph sufficient to vaccinate at least a dozen children. When about to use it, the pen part is reversed, as seen in the figure, and a scratch is made (which carries the vaccine virus to the desired spot). For greater certainty, a second short scratch may be drawn across the first, thus, X. For vaccinating from arm to arm nothing could be better—as the instrument charges itself. It also serves to open ripe vesicles, to charge Dr. Husband's capillary glass-tubes, and it will carry several of these at the other end, so that a school or a good-sized vaccinating station can be served with this pocket instrument. There is nothing in it to alarm

either mother or child. It is neat, portable, efficient, and bloodless. We therefore confidently predict a large sale for this little weapon.

MISCELLANY.

MEDICINE IN RUSSIA.—The Russian *Golos* contains some medical statistics, from which it appears that in Russia there is only one physician to 17,800 people, whilst in Italy there is one to each 2,280. There are some governments, such as that of Tcherdinck, where the proportion is even lower, and there is only one healer of the sick to each 60,000 inhabitants. The surgeons are more numerous, and average one to each 12,400 inhabitants. Of hospitals there is only one for each 175,000 inhabitants, who, from the distances at which they live from the institution, are not likely to abuse the privilege of out-patient relief. In Prussia they are rather better off in this respect, having one hospital to each 22,000 of the population. One lying-in hospital must suffice for each 1,000,000 Russian women, one foundling hospital to every 1,350,000 of the inhabitants, one lunatic asylum to each 90,000, and one deaf and dumb asylum for each 11,000,000. The army medical service is far more in accordance with the wants of that body of the population, since there is a hospital for each 5,000 soldiers, whilst in Prussia there is one for every 1,250.

LEAD IN SODA-WATER (CONVICTION).—It is satisfactory to find that the law is not altogether inadequate to protect the drinkers of aerated waters if it be properly put in motion. At the Dumbarton Police Court, before Bailie Buchanan, James Ewing, manufacturer of aerated waters, was charged under the Food Adulteration Act with having sold as genuine a bottle of soda-water, which was simply pure water charged with carbonic-acid gas, and which also contained one-tenth of a grain of lead per gallon, which rendered the use of the water injurious to health. He pleaded not guilty, and affirmed that he had made his soda-water in precisely the same manner as all other makers. He said there had not been until recently any other way of making these waters except by charging water with carbonic acid gas, and that soda was not put into them unless specially arranged for. When the matter was brought under his notice he had got his machine altered as soon as possible, and the waters were now all right. Mr. McKay, the prosecutor under the Food Adulteration Act, said that some time ago he had got samples of soda-water from the makers in town and sent them to the public analyst (Dr. Clark, Glasgow), who reported that they contained no soda, and also that he found a quantity of lead, which would prove injurious to health. Mr. Ewing had said that he believed the lead might have been originally in the town's water and not caused by his machine. Mr. McKay had a sample of the town's water, which had to pass through a leaden cistern analysed, and it had been found to be perfectly pure. The accused said he did not doubt that lead had been found in his soda-water, but the same thing had been the case wherever it had been analysed. That, however, would be prevented in future. He then withdrew his plea, and pleaded guilty, when he was fined 1s., with 2s. 10s. of modified expenses.

THE CORONERSHIP FOR CENTRAL MIDDLESEX.—For the vacant office of Coroner for Central Middlesex a sharp contest is, we hear, likely to occur between members of the medical and legal professions. The most prominent medical candidate is Dr. Hardwicke, who has been favourably known for several years as the deputy coroner, on Dr. Lankester's appointment; also as medical officer of health and public analyst for Paddington, and secretary of the public health section of the Social Science Association. Mr. Granville, a gentleman of medical qualifications, and formerly editorially connected with the *Globe*, is also a candidate. On the legal side Mr. Serjeant Sleigh, and Mr. C. J. Lewis, M.P., who contested the election with Dr. Lankester, and was defeated by a narrow majority, are announced as candidates. The Middlesex magistrates are, it is stated, as a body, much in favour of a legal appointment; but on the other hand the impression is gaining ground, we think, that an inquiry into the cause of death, which has often to be conducted without legal assistance, and in the presence of medical evidence, often on one side only, is best conducted by a judge who has medical knowledge, by which to check the statements and opinions of the medical witness. Without such knowledge a coroner is often helplessly in the hands of the medical witness, who can impress on the coroner and jury whatever verdict he wishes. A legal coroner is in the majority of cases compelled to take the whole of the facts and conclusions from the medical witness, often the most interested person, and his verdicts are nothing else than a record of that evidence, which no one in court has the knowledge to criticise or check. This is not a satisfactory state of things, and we are strongly of opinion that in a great number of cases no other than a medical coroner can afford the necessary safeguard which an inquest is intended to afford.

WHY THE CHAMELEON CHANGES COLOUR.—At the meeting of the Société de Biologie of Paris, of October 17, M. Paul Bert discussed the cause and mechanism of the changes of colour in the chameleon. The animal is normally of a dark bottle-green colour, which changes

to pale green and then to very pale yellow. The causes of these changes of colour should, he said, be sought for in the nervous system exclusively. If the sciatic nerves of the left side of the chameleon be cut, the side on which the division is made will take on the darkest shade of green, whilst the other side will become lighter. The nerves to which the changes of colour should be referred take their rise directly from the encephalon, and follow the same direction as the motor nerves, for if the chameleon be poisoned with curare it becomes black, and if it be chloroformed it becomes lighter in tint; whilst, if the experiment be carried further and it be killed with the latter anæsthetic, it then turns black. By taking away the two halves of the encephalon and leaving the nucleus, the animal changes colour and becomes very dark. If, on the contrary, one hemisphere of the encephalon be left, the chameleon remains light coloured on one side, whilst the other side becomes darkened. It is therefore evident that there exist what may be termed colouring nerves, setting out from the nucleus of the encephalon, the two hemispheres of which are destined to moderate the nerve-action and to give a greater or less intensity to the tints of the chameleon. The mechanism of these changes has been thus explained by MM. Milne Edwards and Pouchet. Under the skin, and communicating with it, are vessels filled with a pigment coursing through little canals which intersect, cross, and interlace each other in all directions at the back of the epidermis itself. This pigment is afterwards drawn back into the vesicles by the volition of the animal, and the chameleon then takes on a pale tint produced by a pale yellow tissue visible by its transparency. M. Paul Bert has also noticed that light excites the colour of the chameleon. Thus, if the animal be disturbed in its sleep during the night, the side illumined by the light becomes pale, whilst the other side remains dark. This influence of light and its power in exciting these changes of colour in the chameleon require elucidation, and may prove to be a starting-point for interesting researches in general physiology.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17s. 4d.: free by post, 19s. 6d.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & Co., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The First Volume, containing upwards of Two Thousand Articles abstracted and compiled by a staff of Fifty Hospital Surgeons and Physicians, is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for the year 1873 are also ready, price 1s. 6d. each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & Co.—Calcutta: THACKER, SPINK & Co.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & Co.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & Co., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S.W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, NOVEMBER 11, 1874.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

CHARPENTIER ON HÆMORRHAGE FROM PLACENTA PRÆVIA.

(Concluded from page 678.)

Treatment.—That plan of treatment which is of service at one period of gestation is useless at another. It behoves therefore to make a careful review of the different methods proposed and the times they are applicable. Bleeding is useless; opium is equally so; cold is no better. There remain but the induction of labour, ergot, plugging, rupture of the membranes, and lastly, a plan recommended by Simpson and Barnes, and adopted by the English, to detach the placenta, and extract it in advance. [This last statement must be startling to English accoucheurs.—*Rep.*] Forced delivery is the most ancient method, and was formerly practised by the hand, one or two fingers being inserted into the cervix uteri; later, the os was nicked in several directions with a bistoury, an extremely hazardous and severe measure, which should only be adopted in extremes when all else has failed. The cervix is frequently lacerated to a great extent.

Puzos never ruptured the membranes until the os was somewhat dilated. This system is called after Puzos, he being considered the first suggester. Such, however, is not the case, as the older authors always treated these cases after this manner (Mauriceau, Dionis, Deventer, etc.); only they did not use gradual dilatation by means of the fingers, as he advised, but excited uterine contraction, when the pains were feeble, by hooking the finger round the os, and dragging on it, with intervals of rest, from time to time. This method is not applicable to complete placenta prævia. Encouraged by the success attending this mode of treatment in partial placenta prævia, accoucheurs were induced to attempt ruptures of the membranes in the complete form; consequently Deventer advised thrusting the finger through the placenta; so did Rigby. Baudelocque, instead of the finger, used a trocar. Gendrin preferred detaching the placenta with his finger in one direction, so as to reach the margin of the placenta, and rupture the membranes. Dubois advised rupture of the membranes only in partial, or very urgent cases of complete placenta prævia. Dr. Charpentier teaches that the membranes in complete placenta prævia should only be ruptured after Gendrin's method, either when the os is so dilated that the termination of the labour can be speedily accomplished, or when the foetal heart indicates danger to the child. The method is contraindicated when the presentation is abnormal; recourse must then be had to other means, and also when rupture of the membranes does not hasten the labour. In the latter case, ergot is of great service; but, from its fre-

quent destruction of the foetal life, it requires great care in its use. It should never be used in contraction of the pelvis, organic lesion of the uterus, or false presentation. But the safest and best treatment is the tampon, which, however, from defective and ignorant application, has not always yielded the results it should do. M. Leroux first brought it into general use. Both Drs. Bailly and Barnes disapprove of it; the latter because he has propounded another method which he thinks superior. The author uses it in the following manner. He strings a number of pieces of charpie together, like the tail of a kite, about twenty in number. The amount necessary is large, rarely less than a pound, and frequently a pound and a half. It is divided into three parts; one third is strung together, the next divided into pledgets, but not tied together, and the last third left as it was. Five or six long compresses, and a T-shaped binder, are also prepared. Before applying the plug, the vagina should be well syringed, so as to remove any clots, the urine drawn off, and the rectum emptied. In applying the tampon, some authors recommend that the pledgets should be dipped in a solution of perchloride of iron; a cerate of cold cream is better. Some pack the os first, and then fill up the *cul-de-sac*; the present writer joins with those who advise the reverse operation. In plugging the *cul-de-sac*, force is not required, but dexterity and gentleness. When the vagina is full, some dry pieces of charpie are applied to the vulva before placing the compresses on. If the external pieces of charpie remain dry, the hæmorrhage has ceased; if, on the contrary, they become moist and stained, the tampon should be immediately removed and another introduced, taking care to squeeze those plugs in contact with the posterior part of the vagina and the neck. The success of the operation depends on this. The operation should be done very rapidly. The tampon should be kept in from twelve to twenty-four hours, and ergot given in certain cases according to circumstances. The method of using the handkerchief or a piece of muslin, as practised in England and Germany, is not recommended, as it prevents ample packing of the vagina, whether the speculum is used or not. The objections to the tampon are these:—1. Transforming an external loss into an internal one; 2. Prematurely inducing labour; 3. Causing great pain; preventing micturition and defæcation, and producing serious ills. The first is unfounded, as, with the placenta adherent to the os, the membranes intact, and the child *in utero*, it is impossible. Any obstacle to the escape of blood favours its coagulation, and so arrests the hæmorrhage. Even if the placenta be detached at certain points, the labour having begun, the blood retained by the tampon forms a clot, and acts as a plug between the tampon and the placenta, the liquid part escaping and distending the pieces of charpie. If the membranes be ruptured, a certain amount of blood escapes into the uterine cavity, but the contraction of the uterus prevents it from increasing to any great amount. Should the head present, it is forced down upon the cervix, and acts as an internal tampon. The uterus, under any case, should be strictly watched, and a tight binder placed round the woman; should the bleeding be found to increase, no time should be lost in removing the tampon and hastening delivery, the cervix being nicked if it present an obstacle to the extraction of the child. M. Jacquemier strongly advocates the tampon if the labour is established suffi-

ciently to keep the hæmorrhage within moderate bounds. The second objection is hardly one, as the hæmorrhage, as a rule, does not show itself until about seven-and-a-half months. The child is viable, and the observations of Dubois, Kock, Lachapelle, Depaul, and Villeneuve have proved that a tampon can, in some cases, remain in forty-eight hours without inducing labour, and even, when labour has set in, without terminating it. The safety of the mother and child should be considered first. As to the last objection, the urine can be easily drawn off; as to the bowels, if the rectum have been previously emptied, there is no necessity of considering them. It should be recollected it is only a palliative measure preparatory to an ulterior one. Dr. Barnes orders the tampon to be removed at the end of an hour, which accounts for the ill-success in his hands. M. Depaul and Pajot advise, if the hæmorrhage have ceased, not to remove the tampon for twenty-four or thirty-six hours, except under particular circumstances. Should labour not have set in, it should be then withdrawn. If, on the contrary labour have begun, the pain being feeble, M. Depaul orders the tampon to be replaced, and to be kept in only a short time, from two to eight hours, and ergot to be given. When the os is thought to be sufficiently opened, the waters are ruptured, and the fœtus is delivered, either by version or the forceps, as soon as the os permits. Should the hæmorrhage re-occur in great quantities, or in a feeble person, or exhausted from loss of blood, the tampon is again to be replaced, and dilatation of the os to be waited for, until it is wide enough to extract the child through it. The membranes in these cases are not ruptured until the moment of extraction. This plan is applicable in every case. M.M. Bailly and Pajot plug the vagina, but, instead of removing the plug when they think the dilatation complete, forcibly retain it by the hand until so much is expelled that the end of the labour must be near; then one or two grammes (fifteen or thirty grains) of ergot are administered. This method greatly increases the mortality of the child, and is its chief objection, besides being inapplicable in many cases. When the waters have broken, and internal hæmorrhage has occurred whilst the tampon was in the vagina, it should be immediately removed, and other means employed. If a woman be much exhausted from loss of blood, and the pains be feeble, the tampon should not be retained in indefinitely until it may have arrested the hæmorrhage, but only be kept in sufficiently long to enable the woman to recover herself a little. It should be then withdrawn, and artificial extraction attempted. The idea that the tampon by its pressure on the cervix prevents its dilatation, is not the case in reality. There is always a space between the tampon and the cervix which is filled with coagulum. M. Bailly's plan is admissible, when the pains are strong, the head presenting, and the membranes intact; the infant is lost, it is true, but the mother is saved. M. Depaul's method is best in the reverse conditions. When it is determined to terminate the labour, the treatment is guided by whether it is a marginal insertion or a central one. If marginal, the membranes should be ruptured, and the hand or the instrument passed; if the pains be strong, and the hæmorrhage slight, and the head press firmly on the cervix, the case should be left to nature. Of the two methods, separating a portion of the placenta so as to enable the hand to rupture the membranes and to seize the child, or tearing

through the placenta, both are very fatal to the child; the former is preferable, and gives the infant a better chance. M. Bailly, out of thirty-two cases, lost seventeen mothers; of the fifteen saved, six were treated by means of the tampon alone; nine with the tampon associated with other methods. In the cases of death, two were treated by the tampon alone, and fifteen by the tampon combined with other methods. Of eleven cases personally attended, he treated five by turning; three recovered, and two died; in six, he used the tampon only; five were cured, and one died. In the Clinique from January, 1852 to January, 1873, there were 16,613 confinements; placenta prævia occurred in sixty-five. Of the mothers, forty-three recovered and twenty-two died; of the infants, twenty-three were saved, and sixty-two died. The modes of confinement were: version in twenty-two cases; the forceps in nine; labour terminated spontaneously in thirty-three, and one died undelivered. The insertion was central in twenty-one, and marginal in forty-four. There were fifty-three multiparæ and twelve primiparæ. Of the thirty-three cases of spontaneous delivery, twenty-five mothers and fourteen infants survived; eight mothers and nineteen infants died. In the twenty-two version cases, thirteen mothers and six infants recovered; nine mothers and sixteen infants died. In the nine forceps cases, five mothers and three children were saved; four mothers and six infants died.

Finally, there remains detachment of the placenta. Radford, in 1844, collected forty cases, and showed that pressure of the child's head upon the placenta was the cause of the arrest of the hæmorrhage, and propounded the six following propositions. 1. Neither the delivery nor the detachment of the placenta ought to be attempted until the os was sufficiently dilated to permit the introduction of the hand without danger. 2. If the death of the fœtus be certain, detach the placenta entirely, replace the membranes, and leave the case to nature if the pains are strong, if not apply galvanism. 3. If the pelvis be retracted, extract the placenta, puncture the head and extract with the crochét. 4. If the os be partly dilated or dilatable sufficient to allow the passage of the hands and the pains are strong and the waters broke, detach and extract the placenta. 5. If there be great exhaustion from excessive loss of blood and the placenta be central, perforate it with a trocar and cannula and draw off the liquor amnii, and then completely remove the placenta and use galvanism. 6. If partial placenta prævia, rupture the waters; should there be hæmorrhage, employ galvanism. Simpson, attracted by this theory, proposed the entire separation of the placenta previous to delivery. He collected an immense number of cases to prove his theory, and showed that where the placenta was spontaneously expelled before the child, the maternal mortality was only 10 out of 129, and of infants, 31 out of 82. Cohen (*Journal für Geburtskunde*, 1855) suggested turning a complete placenta prævia into a partial, by detaching one-half and allowing it to hang down in the passages. Bunsen proposed only partial avulsion of the placenta; he states that it stops the hæmorrhage, and does not prevent the child going its full time. Lastly, Dr. Barnes's method, which is too well known to need explanation, consists in detaching the placenta from the placental zone.

In conclusion, version is found the most fatal to mother and child, the forceps less so, and spontaneous

delivery the least so. It is therefore desirable, whenever possible, to leave the case to nature, and only to interfere when the life of the mother or child is imperilled.

W. C. GRIGG, M.D.

ON THE TREATMENT BY MINERAL WATERS OF CHRONIC DISEASES, AND ON THE PRINCIPAL SOURCES ADAPTED TO THE VARIOUS MORBID CONDITIONS. BY M. GUBLER.*

(Continued from page 694.)

X. Treatment of Urinary Gravel.

The physician has to treat two principal forms of gravel, the lithic acid, and the phosphatic. Oxaluria is comparatively rare, and its treatment is essentially the same as that of the first form of gravel.

For the lithic, that is red gravel, there are two modes of treatment, the preventive, and the curative. The first is the treatment of the lithic acid diathesis, and will be treated under the head of gout. I shall now merely indicate the waters which act directly on gravel. For subjects who are robust and plethoric, at all events in fair condition, one may boldly order the strong alkaline waters of Vals or Vichy, or the analogous weaker ones of Soultzmat and Marcols, also those of Boulou and of Neyrac, where there are establishments. The three last are suited for patients who are somewhat under par, as they contain a little iron. But in the case of patients decidedly broken down and anæmic, the strong alkaline waters are too depressing, and we must employ some harmless waters in large doses, which may, as it were, wash out the kidneys and urinary passages. Such are the indifferent waters of Evian or Amphion, or the mixed waters of Contrexéville, Martigny, and Vittel in the Vosges, or those of Pougues.

Some of the more slightly sulphurised and weakly alkaline springs of the Eastern Pyrenees may suit, especially if the gravel is attended with a considerable amount of vesical catarrh.

In the case of phosphatic gravel, which is seldom a primary formation, but almost always a consequence of other lesions of the urinary organs, attended with purulent catarrh and alkaline urine, Moltig, Olete, and La Preste in the Eastern Pyrenees, render the greatest service. In similar cases, the degenerated sulphur waters seem to have the advantage over others, of reducing the secretion by acting on the mucous membrane, and preventing ammoniacal fermentation of the urine.

Evian, Contrexéville, Vittel, and Pougues are all useful in catarrhal affections of the bladder, with or without the complication of phosphatic gravel. The strong alkaline waters would only be injurious.

[There is no allusion in this section to any German waters, not even to those of Wildungen, or of the now less known Heilbrunnen, whose larger proportion of iron distinguishes them from most waters employed in this class of diseases, and makes them especially suitable in anæmic cases.—Tr.]

XI. Treatment of Gout and Rheumatism.

Closely connected with lithic acid gravel is gout, the chief characteristic of which is the presence of an excess of lithic acid and of the lithates in the

blood and humours. There is the most entire discordance among the most eminent physicians respecting the treatment of gout; some having great faith in pharmaceutical remedies and in mineral waters; some having none. These differences of opinion can only be explained by supposing, that different conditions are represented by the one name of gout.

In order to make a judicious use of our remedies, we must discriminate each case. Nothing but hygiene and regimen can be opposed to the gouty diathesis itself. An access of acute gout must be treated at home, like one of acute rheumatism. But the moment the case becomes subacute, mineral waters are applicable, as the diuretic ones of Evian, of the Vosges group, or the soothing baths of Bagnères, Adour, Bagnoles (Orne), Nérès, Ussat, and some others. Chronic lesions, the effects of repeated attacks of gout, thickening of the fibro-synovial membranes, stiffness of the joints, and atrophy or hypertrophy of the muscles corresponding with them must be attacked with the stimulant baths of thermal stations, and especially such as are sulphurous; Barèges, Aix-les-Bains, Cauterêts, Ax, Luchon, Le Vernet. Only when topi are present, or in any case where the tissues altered by gout are irritable, the ordinary treatment by *massage* (shampooing) should not be carried out. As for the excess of lithic acid, which is the basis of the constitutional affection, we must modify it as we have already explained under the head of lithates, sometimes by alkaline waters, sometimes by the indifferent and slightly mineralised ones, always having regard to the patient's condition. The same principles are applicable to the treatment of rheumatism. Acute rheumatism is no subject for mineral waters; the subacute forms will only bear soothing baths and diuretic waters. The application of mineral waters is oftenest required for chronic alterations of the joints, and changes in the muscular and fibrous tissue; and the hottest waters in their various modes of application give the best results.

The chemical composition of waters has really not much to say to the therapeutic effects, and the indifferent waters of Plombières, Bains, Luxeuil, Nérès, or the salt waters of Balaruc, Bourbonne, Bourbon l'Archambault, and the mixed ones of Chateaufort, Mont Dore and Saint-Nectaire, are as effectual in chronic rheumatism, as the sulphur waters of Bagnols, Aix-les-Bains, Luchon, Barèges, Gréoulx, etc.

Nevertheless, the mineralisation is not entirely a matter of indifference. Waters which contain sulphur, or a good deal of chloride of sodium, or which are highly charged with carbonic acid, add the special stimulation of those substances to that which results from a high temperature, and suit best torpid constitutions and old lesions, in cases which have had no recent paroxysms. Waters weakly mineralised are better suited for cases, where the inflammatory action is only lulled, and when the subjects are irritable.

But in spite of their different degrees of mineralisation, all the baths frequented by rheumatic patients may, by various modifications of the method of applying the waters, be adapted to each variety of morbid form. And practically we are often obliged to recommend baths, not according to their mineral contents, but according to their proximity or distance, the nature of the bath establishment, or the elevation and climate of the station. Supposing that we could always take into account all the

* *Journal de Thérapeutique*, no 10 et seq.

various requirements of the general health, and of internal treatment, we might make a more discriminating selection among the waters we have enumerated, and send those who suffer from eczemas or from scrofula, to the strong saline or well sulphuretted waters, and especially to the sulphur-waters containing chloride of sodium, and iodine and bromine, of the Basses Alpes. Anæmic and cachectic patients might be sent to the complex and restorative waters of the centre of France. In the thermal baths just enumerated, rheumatic patients also often find great relief in some stations, from the deposit from the waters, chiefly accidental sulphurones.

Mineral mud is now very little used; yet prolonged illutation or poulticing with the mud is of great service in swellings of the joints, in old muscular contractions and paralysis. The length of time during which it is kept on makes up for the weakness of the topical application. Time takes the place of temperature. Baths of mineral mud, such as are used at Franzensbad, Marienbad, and at Acqui in Italy, are supplied to us in France in various localities. The principal are at Saint-Amand, and illutation is practised in a special form at Barbotan, Aurensan, Saubuse, and Dax, there are mud-baths at Aix in Savoy, Bourbonne, and Uriage, where their topical action, at once relaxing and stimulating, co-operates with the high temperature of their waters.

[It may be conceded to M. Gubler, that France is amply supplied with waters for the thermal treatment of rheumatism and gout; but the number of such waters in other countries, visited by hosts of patients, is so great, that at least some of them might have been mentioned. There is some misapprehension about the mud-baths of Marienbad and Franzensbad, which are compared with those of Acqui. But the artificially prepared earth of the German mud-baths cannot well be classed along with the natural deposits or *fanghi* of Acqui, Apona, and other places.—*Tr.*]

XII. Treatment of Paralysis.

Purgative mineral waters taken at home, are the only ones that a physician can prescribe in cases of recent paralysis, due to a lesion of the encephalon or of the spinal cord—to hæmorrhage, or to inflammatory action. A true physician will never think of sending to mineral waters a hemiplegic or paraplegic subject, in whom the causal lesion has not completed its course, and whose condition might be greatly aggravated by the thermal excitement, and the fatigues of a cure. But how long are we to abstain from them? Are we to wait only for the cessation of the symptoms of irritation, and for the absorption of the effused blood, or are we to wait for an entire disappearance of the altered condition of the cerebral tissue around the effusion, the formation of a cicatrix, solid or cystic, but entirely devoid of irritability? Competent men do not hesitate to undertake a mineral-water course at a very early stage, which may, in their skilled hands, be safe. But I confess that, where the results are so uncertain, I do not recommend precipitation.

The stimulating treatment of Balaruc, Bourbonne, Bourbon l'Archambault, is only to be recommended, when all signs of irritation have disappeared in a case of hemiplegia, and when there are no symptoms that might indicate a possible return of congestion, of hæmorrhage, or of softening of the nervous centres.

The rule for paralyzes of cephalic origin, applies also to those of spinal. Peripheric paralyzes, those from cold and from rheumatism, have also their periods of excitement, and must have thermal treatment applied with similar reserve.

To sum up, paralyzes consequent on acute diseases, hysteric paralyzes, and those from lead and metals, can scarcely fail to profit at La Malou, at Balaruc, Bourbon l'Archambault, Bourbonne, Saint-Nectaire, or at Aix-les-Bains, Bagnols, Barèges, as also by the illutation practised at Barbotan, Dax, Saint-Amand, and some other stations. Rheumatic paralyzes which have become torpid gain by the same treatment, and so do old paraplegias and hemiplegias, when they have no symptoms of irritation.

But all that is really to be expected, is the re-awakening of the cutaneous sensibility, the increasing of the activity of the capillary circulation, favouring nutrition, and restoring muscular contractility. Mineral waters, like other remedies, have no direct action on cephalic or medullary lesions. The mineral-water cure is simply palliative, retarding the atrophy of paralysed limbs, and hastening the restoration of their motor functions.

We can thus easily see, how mineral waters are usually powerless in the case of some cerebro-spinal affections which are essentially progressive, as infantile paralysis, locomotor ataxia, and spinal softening. Nevertheless, I think it is worth while to have recourse to them, before all therapeutic means have been exhausted. Occasional successes, obtained without doubt in the period of mere neurosis, with simple molecular alteration, and more numerous cases of amelioration in advanced ataxia, the consequence of thermal treatment, especially at La Malou, supply very real grounds of encouragement for making a further trial of such treatment.

XIII. Treatment of Albuminous and Saccharine Diabetes.

The albuminuria of Bright's disease is in reality just as much a constitutional affection as glycosuria. Results of analogous causes, and presenting similar morbid phenomena, they yield to the same therapeutic agencies, thus showing how closely their pathology is allied.

When there is no primary nephritis, the presence of albumen in the urine, like that of sugar, indicates a relative excess of that protein principle, taking into account the expenditure, and the proportion of blood-corpuscles, on which it is dependent; whether the excess is caused by a diminution of the blood-corpuscles, or by the introduction of an exaggerated quantity of albuminous articles of food; or whether it depends on some obstacle to blood-making, or on some retardation in the nutritive and formative processes. The similarity of causes points out similarity of treatment; and in both affections I recommend abstinence from articles of diet containing an excess of albumen, moderation in eating, muscular exercise, life in the open air, and all conditions favourable to complete respiratory action, and to the restoration of the system; fourthly, the use of certain blood-making and nutrition-promoting medicines, such as iron and manganese, and at times arsenic or other substances which have the power of modifying nutrition and the constitution of the blood. Among these curative agents there are none superior, indeed, none comparable, to the mineral waters.

Vichy has long established its fame in saccharine

diabetes, and Vals, and other more or less strong alkaline waters, have done the same. Do these waters act by compensating for deficient respiratory combustion, as M. Mialhe thinks, following M. Chevreuil's beautiful experiments on the action of the presence of alkalis in the conflict of oxygen with combustible matters, or do they somehow moderate the functional activity of the liver, according to the celebrated doctrine of the sugar-making property of that organ? Do they not more probably, as I think, act by stimulating the cells of the parenchyma of the principal blood-making gland, and by ensuring the assimilation of the ternary products required for the formation of some tissues, and especially the muscular fibre? The reply to this is doubtful; but if the theory is so, the fact remains positive, and is confirmed by every-day experience, that there is a considerable reduction of the amount, if not entire withdrawal of sugar from the urine, under Vichy treatment. But this cure only suits florid diabetes, that is, the disease when it occurs in those who seem to enjoy robust health, as is usually the case.

But when there is anæmia, with defective nutrition, or when the glycosuria is associated with pulmonary tubercles, then strong alkaline waters cannot be prescribed in large doses, or for any length of time, without extreme danger. In such cases shall we content ourselves with small doses of the strong, or with the feebler alkaline waters? I think not; even small doses of alkaline waters would only increase the general cachexia.

The good effects of that splendid station Carlsbad need not be considered as militating against this, if we take into consideration the complex mineralisation, as well as the feeble alkalinity of its waters.

What anæmic cases of diabetes require, are the restorative waters, the normal *protogéniques*, as I have called them, at once to remind us of their origin, and to show both that they afford all the mineral materials required for the animal structure, and that they are the ordinary types of waters arising from the deeper strata of the earth. Rouzat, Saint-Maurice, Vic-le-Comte, Chateaufort, Saint-Nectaire, La Bourboule, and even Chatel Guyon, in spite of the absence of soda, are all indicated as substitutes for Carlsbad. Indeed restorative effects are more easily procurable from the French waters, as they have not the troublesome laxative effects of Carlsbad. Bourboule, too, would stand at the head of all mineral waters in saccharine diabetes, if it were once really proved that arsenic has the power of diminishing the proportion of sugar in the urine.

Chronic albuminuria, which is of course its only form for mineral-water treatment, has for a long time been regarded only as the expression of a renal affection, necessarily progressive and fatal. But the theory of albuminuria suggests the use of the restorative waters I have just enumerated. I used formerly to prescribe the use of imported chloride of sodium and sulphate of soda waters, before recommending a course of waters in the centre of France; but of late years I have been satisfied that many patients suffering from albuminuria have derived advantages from them, such as they could not have received from any pharmaceutical treatment. In purgative and alterative doses, the waters of Chatel Guyon have produced excellent results; among others, in a case of Bright's disease with anæmia, anasarca, and abundant desquamation of the tubuli. Favourable changes have been obtained under similar circumstances at Saint-Nectaire and at La

Bourboule. I have no doubt that Saint-Maurice, Saint-Myon, Rouzat, and Chateaufort would do similar service; but Saint-Nectaire appears to me to be the most complete type of those mineral *lymphs*, of which Carlsbad is a fine foreign specimen. The normal proteogénic waters possess, in my opinion, a double medical action. Not only do they repair the losses of the neutral salts of the serum, and give activity to the blood-making process, but also by the superabundance of mineral riches which they supply, they augment the capacity of the blood for albumen, and thus prevent its escape by the various channels of elimination. But to produce these effects the course of waters must be somewhat prolonged, and not shorter than four or five weeks.

[If such effects can really be obtained from them in glycosuria and albuminuria, M. Gubler is entitled to be in raptures over the waters of central France. No doubt they are an interesting and important group; and, without accepting far-fetched notions about primary rocks and mineral lymph, it must be admitted that the waters of Saint-Nectaire and of Royat are good alterative tonics. It seems to be certain that the waters of Bourboule do really contain an unusual quantity of arsenic, and the station is rising rapidly in importance. The accounts of local observers appear to be silent, or all but so, as to the good effects of these waters in the cases now treated of by M. Gubler.—*Trans.*]

XIV. Treatment of Skin-Complaints.

No more than ordinary medicines, are any mineral waters really specific in chronic skin-affections. Each has its special indications with reference to its physiological action. But the same indications often arise in the course of affections that may be very different as to their primary cause, and varied remedies may be required by the same case during its different stages. We must therefore not be surprised to find the same water ordered for very different affections, and the same affection treated by very different waters.

In selecting a place for a cutaneous affection, we must consider on one hand the extrinsic or diathetic cause, on the other hand the anatomical condition of the lesion. If it be a case of parasitic dermatosis, psora, herpes circinatus, pityriasis versicolor, etc., we prescribe the strong sulphur-waters of Challes, Barèges, or Luchon, which are eminently toxic to the lower organisms of both kingdoms.

Gouty dermatoses, when they depend on excess of lithic acid, are advantageously modified by alkaline waters. Strunous dermatoses are sent, according to the case, to two classes of waters—the chloride of sodium waters with iodine and bromine, or the sulphur ones. It is admitted generally with M. Bazin, that the true *herpétides* are especially under the influence of arsenical waters. But I beg to remark, that this class of waters is not a very natural one, that its characters are in great measure negative, and that so many other elements are present along with the arsenic, that it is difficult to speak positively of the action of the latter. Syphilitic eruptions will be discussed afterwards.

The different forms of cutaneous affections require different waters. Thus moist eruptions do best with sulphur-waters; hypertrophic or ulcerating lesions are best treated by the salt and iodine waters; while the dry squamous affections require the use of

protracted baths, a sort of slow maceration, as much in indifferent ones as in those of special mineralisation. So to say, patients are most readily cleansed by salt or alkaline waters, or by sulphuro-bituminous ones, having a distinct local action.

Dry scrofulous skin affections, in the form of lichenoid eczemas, of lichen, of tubercles, and squamæ, should be treated by the salt waters of Salies, the two Salins, Balaruc, Bourbonne; moist eczematous or impetiginous ones, should first be sent to Pyrenean stations, to Barèges, Ax, Luchon, or, still better, to Digne and Gréoulx. Uriage is, owing to its laxative qualities, suited specially for lymphatic scrofulous patients, and so also Saint-Gervais, where the separation of the purgative and the sulphur wells, facilitates the employment of whichever is most indicated.

Arthritic eruptions may be divided among the pure alkaline waters of Vals or Vichy, or the mixed ones of Auvergne, Royat, Rouzat, Saint-Maurice, La Bourboule, and the lighter distinctly alkaline sulphur waters of the eastern Pyrenees, Moltig, Olette, La Preste.

If the eruption is at all acute, or there is irritability of the skin, I prefer the milder waters of each class, such as those of Moltig, or the weaker sources of Ax, Luchon, or Cauterêts, or even the sulphide of calcium ones, chiefly containing sulphuretted hydrogen, as Enghien, Saint-Honoré, Guillon, Allevard. In some cases we may be content with the indifferent waters of Plombières, Bains, Nérès, Ussat, Bagnères de Bigorre.

On the contrary, inveterate affections, usually of the squamous form, such as lichen, lepra, psoriasis, require the protracted use of strong waters, and improve at Bourboule, Gréoulx, and also at the sulphuro-bituminous sources of Saint-Boès and Euzet. Excessively prolonged immersion even in waters of feeble mineralisation, produces powerful stimulant effects, resembling those of stronger waters. Owing to this topical irritation, and the *poussé* which is the consequence of it, one sees eruptions, which have remained stationary in spite of the most rational treatment, change their character in the baths of Leuk in Switzerland. The same results might be obtained at many other stations, especially those where they practice illutation, as Saint-Amand, Dax, and Barbotan.

(To be concluded.)

ANATOMY AND PHYSIOLOGY.

KNOLL ON REFLEX EFFECTS ON BREATHING, PRODUCED BY INTRODUCTION OF VOLATILE SUBSTANCES TO THE AIR-PASSAGES UNDER THE LARYNX.—In the *Sitzungsberichte* of the Vienna Academy (Band 68, Heft 4 & 5), Dr. Knoll, of Prague, has a paper on this subject. The fact that the temporary state of expansion of the lung is sufficient of itself so to excite the vagus, that it calls forth inspiratory, or (more generally) expiratory movements, in a reflex way, led him to expect that by various other natural stimuli of the pulmonary ends of the vagus, similar actions would be produced. The question was interesting, both as regards the theory of respiration, and from a practical point of view. Dr. Knoll's experiments were made on small dogs; the stimuli used were chloroform, ether, benzin, mustard-oil, ammonia, and car-

bonic acid. The nasal mucous membrane was carefully guarded against their action. The author's results are thus stated.

1. Inhalation of chloroform or ether vapour produces, by reflex action through the vagus, acceleration and shallowness (*Verflachung*) of the movements of respiration, with a deeper position of the diaphragm.

2. Inhalation of benzin or mustard-oil vapour, the vagi being intact, produces the same reflex changes.

3. If a dog, with intact vagi, inhale from a weak ammoniacal solution, the effects are the same. If a strong ammoniacal solution be used, there occur, alternately, a considerable retardation, deepening, and long-continued cessation of breathing in the position of expiration, and acceleration and shallowness of the respiratory movement, in the position of inspiration. The whole series of phenomena depends on reflex action by the vagi.

4. Apnoea, produced by the introduction of chloroform or ammoniacal vapours, continues afterwards. The first breathing movements produced after disappearance of the apnoea are governed by the reflex action on the breathing, produced by the stimuli.

5. If a dog, with intact vagi, inhale pure carbonic acid, or a mixture of atmospheric air and carbonic acid, no phenomenon occurs which can be entirely explained by a direct excitation of the vagi by carbonic acid.

If, now (adds Dr. Knoll), we consider the action of these substances (as described) on introduction of them into the air-passages under the larynx, and, on the other hand, their previously described action on application to the nasal mucous membrane, it appears, that from different points of the air-passages, we may, by these substances, produce reflex effects on the breathing, which may be very different according to the nature of the substances used, and the place of application. If we further consider that some of these substances, after being received into the blood, call forth considerable changes of another kind in the respiration, we are able to comprehend how, with the usual mode of employing these substances for medical treatment (chloroform *e.g.*), there occurs a perfect tangle of phenomena; and only if we can accurately discriminate what, in this tangle, is attributable to a reflex action by the nasal mucous membrane, what to a reflex action by the deeper air-passages, and what, finally, to the reception of these substances into the blood, will it be possible for us to understand the mass of various and apparently conflicting observations which have accumulated with reference to the changes in respiration produced by inhalation of those volatile substances (especially chloroform).

KUNKEL ON THE DEPENDENCE OF PERCEPTION OF COLOUR ON THE TIME.—In a recent number of *Pflüger's Archiv* (vol. ix.), M. Kunkel describes some experiments made, in order to measure the time which is necessary for particular colours of the spectrum, especially red, green, and blue, to have their greatest action. The following results were obtained.

1. The different parts of the spectrum take different times to produce their maximum of excitation; and, in all cases, the time taken by red is the shortest; then follow blue and green, of which, with equal subjective brightness, blue has the precedence. Thus, *e.g.* to produce the maximum excitation (with equal breadth of the slit admitting the light), red

required 0.0573 second; green, 0.0971 second; and blue, 0.1018 second. With about equal brightness, the numbers obtained were, for red 0.0573, for green 0.133, and for blue 0.0916.

2. For the same colour it holds good, that the greater brightness takes a shorter time to produce the maximum of excitation than the less. This appears clearly from the following table:—

| Colour. | Degrees of Brightness. | | |
|-------------|------------------------|----------------------|----------------------|
| | 1 st Sec. | 2 nd Sec. | 4 th Sec. |
| Red . . . | 0.071 | 0.0573 | — |
| Green . . . | 0.133 | 0.097 | 0.0699 |
| Blue . . . | — | 0.102 | 0.0916 |

3. With the brightness vary also colour tone and saturation. This fact (the author adds) has already been experimentally proved by Helmholtz, and may be expressed by the statement, that with increasing brightness of coloured light, the sensations called forth tend towards the white. M. Kunkel observed that blue, without change of its colour-tone, passes into white, whereas green and red approximate to the white through yellow.

He further observed here a marked influence of time on the perception of brightness and of colour-tone. It appeared, especially in the case of green, that the intensities of the coloured light, with short time of action (as much as was necessary to produce maximum excitation) produced uncommonly high values of excitation, and an extensive change of colour tone, whereas the same parts of the spectrum with the same objective brightness, but with continued looking, excited the eye much less intensely, and thus always made the impression of the colour belonging to that portion of the spectrum with great saturation.

4. With very short action of homogeneous light on the eye, the colour-tone is also altered, and in such a way that the whole spectrum now appears divided into two parts, one of which gives the impression of red, the other that of blue. If the excitation be made in still shorter time, or with less intensity, we come to a point where there is perception of light but no perception of colour. Only the red end of the spectrum behaved differently to M. Kunkel's eye; here there was always a perception of colour.

RAEHLMANN ON SENSIBILITY OF THE EYE IN DIFFERENT PARTS FOR DIFFERENT COLOURS.—In order to measure accurately the sensibility of the eye for different colours (which is known to be variable), M. Raehlmann adopted the following method (*Graefe's Archiv für Ophthalmologie*, vol. xx. part I).

A bundle of solar light is reflected from a mirror into a tube at such an angle that it is polarised; the polarised bundle is then decomposed by a prism, passes in a tube, through two movable slits, by means of which portions of the spectrum may be cut out, and then reaches two Nicol prisms, the position of which relatively to each other indicates the intensity of the coloured light from 0 up to 1 through a series of intermediate degrees. The observer begins with a position of the Nicols, in which all the light is extinguished; and then one of them is turned round, until the first sensation of light is perceived; the corresponding intensity is indicated by the angle which the Nicols make with each other. The intensity of light was measured in the case of the several rays, and the results fully agreed with those

reached by M. Lamansky, by a different method. M. Raehlmann's conclusion is, that the eye shows a greater sensibility for waves of mean refrangibility, for the middle of the spectrum; that the sensibility decreases towards the sides, and is least at the ends of the spectrum, at the extreme red, and the extreme violet. It further appeared that there was less sensibility for the last and still visible red rays than for the extreme violet rays.

M. Raehlmann then experimented on the sensibility of the eye for the different colours, at different parts of the retina, and found, that at the periphery of the latter, the sensibility is quite different from that at the centre. Thus the sensibility for red at 30° from the middle of the retina was about $\frac{1}{13}$, and at 60° = $\frac{1}{4}$ of the sensibility of the centre. In the case of yellow the difference was least; blue came next; for green it was considerable, thus at 30° the sensibility was $\frac{1}{3}$ rd, at 60° only $\frac{1}{6}$ th of the central sensibility. For violet there was at 30° a still greater sensibility; while at 60° the sensibility was nearly equal to that at the centre. While a considerable margin must be left for errors of observation, the changed sensibility at the periphery of the retina was satisfactorily established, and it must result in a variable perception of the primary colours.

MATHIEU AND URBAIN ON THE PART PLAYED BY THE GASES IN THE COAGULATION OF THE BLOOD.—In a paper communicated to the Academy of Sciences at the meeting held on September 14, 1874, MM. E. Mathieu and V. Urbain state, as the result of their experiments: 1. That carbonic acid is the agent of the spontaneous coagulation of the blood; 2. That during life the obstacle to this coagulation resides in the blood-corpuscles, these having as their special function the fixation not only of the oxygen, but also of the carbonic acid contained in the blood. As a result, the coagulating action of the last-named gas cannot be exerted in physiological conditions. They proceed to show that there are many proofs of the participation of carbonic acid in the phenomena of the spontaneous coagulation of the blood. Thus, the amount of carbonic acid contained in blood before coagulation, and after coagulation, was at 100° F., 48.05 and 39.38 cubic centimetres; at 86° F., 50.00 and 44.85 cubic centimetres; at 59° F., 49.00 and 40.95 cubic centimetres; and at 50° F., 54.50 and 42.50 cubic centimetres. Again, the blood which returns from glandular organs, and especially from the kidneys, is incoagulable, and this blood contains very little carbonic acid (renal arterial blood 49.78 cubic centimetres per cent., renal venous blood 16.00 cubic centimetres per cent.). So also, if the removal of carbonic acid from the blood be favoured by simple exosmose, coagulation will not take place: yet if it be placed in an atmosphere of carbonic acid, coagulation rapidly sets in. The clots, however, are softer than those which form in air, rendering it probable that oxygen influences their consistence. Lastly, certain neutral salts impede or prevent coagulation, but such salts fix a notable volume of carbonic acid, and thus withdraw it from the blood.

NAWROCKI ON THE CONDUCTION OF SENSORY IMPRESSIONS IN THE SPINAL CORD.—Herr Nawrocki states in a paper published in *Ludwig's Arbeiten aus der Physiolog. Anstalt zu Leipzig für* 1872, that in 1870 Miescher arrived at the conclusion that the fibres of the sciatic nerve, which can produce

elevation of the blood-pressure by reflex action, run, after their entrance into the cord, in the lateral white columns. Several years previously, Türck had maintained that these columns contained sensory fibres. The researches of Miescher left it doubtful whether a portion of the sensory fibres acting upon the muscles of the vessels did not run in the grey substance of the spinal cord. Nawrocki's experiments were undertaken with the view of determining this point, and he has satisfied himself that all the fibres of the sciatic nerve, which reflectorially effect increase of blood-pressure, ran upwards within the upper segment of the lumbar region of the spinal cord in the lateral white column.

HEUBACH ON THE ACTION OF QUININE ON THE NERVOUS SYSTEM.—H. Heubach (*Centralblatt*, no. 43) has repeated Eulenburg's experiments (*Reichert und Du Bois-Reymond's Archiv*, 1865). The author employed a subcutaneous injection of the weak basic amorphous muriate of quinine, which is easily soluble in an equal weight of water. The following results differ from those of Eulenburg. 1. Small doses do not diminish, but increase the reflex excitability. 2. By large doses the reflex excitability is at first increased, and then diminished; still this diminution is to be viewed as a consequence of cardiac paralysis. 3. Very large doses influence not only the respiration and action of the heart, but extinguish very rapidly all signs of life, and therewith the reflex excitability.

With regard to the cause of death in poisoning with quinine, the author finds, as well in frogs as in mammals, that the respiration stops first, and that the paralysis of the heart occurring in consequence can be hindered by artificial respiration. Death from quinine, therefore, is not due to direct poisoning of the heart; but in the first place, to paralysis of the respiration, although the heart is also paralysed by quinine though later than the respiration.

W. STIRLING, M.B.

WILLIAMS ON THE ACTION OF BILE IN PROMOTING THE ABSORPTION OF FATS.—C. H. Williams (Royston Essay, first prize, *Boston Medical and Surgical Journal*, May 7), has made several experiments on this subject by ascertaining the pressures required to force oil through membranes when they were dry, when moistened with water, and when moistened with oil. He also employed thin plates of plaster of Paris instead of membranes in some of his experiments, as the pores in the plaster are rigid and cannot alter in shape. From these he arrives at the following conclusions. 1. The passage of neutral fats through capillary canals or pores is favoured by the presence of bile in those pores. 2. This action is increased when the bile is rendered alkaline, and diminished when it is acid. 3. The action cannot be due to the bile changing the form of the pores. 4. After passing through membranes moistened with bile, the fats appear more finely divided than with membranes wet with other substances, apparently showing that the drop-tension or cohesion of the fat has been affected.

GARLAND ON THE ACTION OF INTESTINAL JUICE. G. M. Garland (Royston Essay, second prize, *Boston Medical and Surgical Journal*, May 7) has obtained intestinal juice from a Thiry's fistula in a dog. The juice was not collected until the animal had perfectly recovered its health after the operation required to establish the fistula. It digested fibrin both raw

and boiled, though it had little action on boiled eggs, and it changed starch into sugar. He seems to have made no experiments himself on the conversion of cane into grape-sugar, but he considers this to be pretty well established by other observers. Microscopic examination of the intestine at the fistulous opening showed no structural change in it except atrophy. The author made the interesting observation that, when the dog was frightened, the secretion of intestinal juice became much diminished.

PATHOLOGY.

ALYSCHESKY ON PARALYSIS OF THE DIAPHRAGM AFTER SECTION OF THE PHRENIC NERVES. Number 35 of the *Berliner Klinische Wochenschrift* (August 31, 1874), contains a paper of considerable clinical interest by one of Professor Botkin's former assistants. It appears that some two years ago Dr. W. Alyschesky published an account of some of his experiments on animals, in Botkin's *Archiv für innere Krankheiten* (Band iv. 1872). These experiments were suggested by an observation made long since by Dr. Botkin, in his clinical lectures, that in patients suffering from typhus fever, the early occurring symptom of weakened abdominal or diaphragmatic respiration is always closely connected with the occurrence of hypostatic congestion in the lower lobes of the lungs. Dr. Botkin often commented on this relation, and he also drew the attention of his class to the fact, that in other cases (especially during the progress of disease) in which other inspiratory muscles were weakened, atelectasis of the lungs sometimes occurred in one part of the lung, sometimes in another. Experimental proof only was wanting of the correctness of Botkin's theory as to the causation of these disturbed conditions of nutrition of the lung; and the carrying out of the necessary experiments in the physiological laboratory was entrusted to the writer of the paper from which we quote. Most of the experiments (which exceeded 120 in number), were made on dogs. The symptoms produced in these animals were ascertained by inspection, percussion, and auscultation. In this way the following results were obtained.

1. Section or removal of a portion of the roots of the phrenic nerves in the neck was followed by complete paralysis of the diaphragm—thus confirming Professor Traube's observations, although contradicting the ordinary notions of anatomists. It was easy to see this by direct observation of the diaphragm, when the abdominal cavity was laid open in narcotised animals. After the section of the phrenics, it was then seen that during respiration

this muscle (the diaphragm) remained perfectly passive, *i. e.* it was drawn into the thorax with each inspiratory act, and pushed back into the abdomen by every expiration.

2. Paralysis of the diaphragm, whether unilateral or complete, is in no way fatal *per se*, for it is fully compensated by the increased activity of the other inspiratory muscles thus induced. Dogs thus treated often recovered so well, that an observer not in the secret would never have known than an operation usually considered dangerous had been done on them. The animals were lively, ran about briskly, and used their voices freely. After a few days, they did not even suffer from dyspnoea.

In every case in which the animals recovered from the first operation, and in which the wound healed, they lived until either purposely killed, or subjected to some fresh experiments. And if the abdominal cavity were laid open whilst such animals were alive, the diaphragm was found to be paralysed.

3. The compensation for the diminished activity of the diaphragm was effected partly by increased rapidity of the respiratory movements, and partly by a greater depth of the separate inspirations; this was most noticeable in young animals with strong muscles and an elastic thorax. In parallel experiments made on dogs by making them a unilateral hydro- or pneumo-thorax, by openings in some of the intercostal spaces—in the first case under water, in the second leaving space for air to enter freely—it was found that the urgent *besoin de respirer* was far greater than that caused by section of the phrenic nerves.

4. Observation by auscultation and percussion in animals with paralysed diaphragms, shows that the lungs still expand in their long diameter, though less than before section of the phrenics. If the pleura be laid bare by removal of the sternum and intercostal muscles, this can be convincingly shown by observation of the upper edge of the liver. This seems at first contradictory of the statement as to the position of the paralysed diaphragm in inspiration, but seems simple enough if we admit, as apparently we must, that the long diameter of the lung is expanded during inspiration, not only by the diaphragm, but also by the contraction of the muscles which expand the thorax. Observation in animals whose abdomen is laid open shows that the paralysed diaphragm is not merely sucked in, as it were, into the thorax, by the action of the other inspiratory muscles—it also becomes broadened, and flatter, and begins to fill the field of the now widened base of the thorax. The diaphragm, which begins below with the lower borders of the lower ribs, both in men and animals, does not at once desert the thoracic walls, but runs at first just parallel with these for awhile, lying close to the costal pleura. According to Luschka and Henle, this immediate juxtaposition (*Anleigen*) of the costal portion of the diaphragm with the lower part of the interior of the thoracic walls may be noted during the great pause following expiration, in the greater part of the extent of the lateral muscular part of the diaphragm, just as in the dead body; so that the pulmonary pleura and the diaphragmatic pleura lie close together for a considerable space. So, when the healthy diaphragm begins to contract, or the paralysed one is passively extended, it is plain that it must first recede from the ribs—and so in fact it does—in consequence of which the points of contact between the costal and diaphragmatic pleurae

are diminished in number, and the so-called negative pressure in the pleural cavity brings the whole process to a conclusion. The lung elongates, the upper border of the liver sinks down, just in proportion to the enlargement of the chest. In consonance with this, it was found that the excursus or movement of the lower border of the lung was least immediately after the section of the phrenic nerves, before the other inspiratory muscles had had time to compensate. Although there is no absolute diagnostic mark of paralysis of the diaphragm to be found by means of noting the percussion-dulness of the upper edge of the liver, and its movements in respiration, yet it is quite true we have diagnostic signs of a morbid condition of this muscle. By percussing the lower border of the liver, Dr. Alyschesky constantly observed a lifting of this during inspiration, and a falling during expiration, in such cases. Professor Botkin demonstrated the same thing to his class, in a clinical on a case of paralysis of the diaphragm.

5. Observation of the immediate effects of section of the phrenic nerves, on the diaphragm, when the parietal pleura was laid bare, or determination of the position of the upper or lower border of the liver during the great respiratory pause (after expiration), constantly displayed an elevation of the diaphragm from one of the lower ribs or intercostal spaces to a higher one; for example, this muscle, before section of the nerves, was noted on a level with the ninth rib, afterwards at that of the eighth rib. The explanation of this must probably be found in the tonicity (*Tonus*) of the diaphragm. If the diaphragm during the expiratory pause were quite flaccid or exhausted, and had no tonicity, the section of the nerves could scarcely render it more flaccid at this period of the respiratory act.

6. A further immediate result of section of the phrenic nerves is the occurrence of a projection of the upper part of the chest on the same side. For experiment, a young dog or rabbit with elastic chest and unossified cartilages, is best. Immediately after section of one phrenic there is a want of symmetry in the upper portion of the chest, even when the pectoral muscles are removed; and during the whole of the respiratory pause, the upper half of the chest on the side of the section is especially prominent. This, and the previously noted condition of the diaphragm, curiously confirm Botkin's views; and we are led from this to admit that there is a constant, although fluctuating state of tonicity (*Tonus*) of the inspiratory muscles of the chest, and consequently of the chest itself, regulated by the nervous system.

7. Section of the abdominal muscles in animals with paralysis of the diaphragm is followed by increased expansion of the lower thoracic region (but not in any marked degree). Dr. Alyschesky explains this by the tonicity of the expiratory muscles, allowing the cervical and upper thoracic muscles to dilate the chest and increase its long diameter, by lifting the upper ribs.

8. Admitting the existence of a constantly acting tonicity (*Tonus*) in the muscles of respiration, explains the otherwise mysterious so-called 'negative' or better 'diminished' (as compared with that of the atmosphere) pressure of the air in the cavity of the thorax. [Our space does not permit us to give the arguments in support of this. The facts relied on are:—that in an eight or eight and a half month's fœtus, careful opening of the thorax through the diaphragm on both sides without wounding the lungs, does not affect a water manometer in the

trachea. In a child four days old, with partial expansion of the lungs, the fluid rose 3·3 millimètres (one-seventh of an inch nearly). *Post mortem* 'negative' pressure is explicable through rigidity of the thorax, and to overcome this stiffening exceeds the elastic force of the lungs.

9. When animals with paralysed diaphragm were killed by pithing, any time from three days to a year after section of the phrenics, there was constantly found more or less atelectatic contraction (carnefication) of the lower lobes, and emphysema of the upper ones. In three cases (out of fifty-six) there was an hypostasis of the lower lobe, once on the right side with double paralysis—twice on the paralysed side in unilateral paresis. The atelectatic lobes were uneven on the surface, generally wrinkled, and the section was firmer and redder than in health—less crepitant, and of greater specific gravity.

10. These experiments induce us to attribute a large share of the congestive (hypostatic) appearances in disease to a weakened or paralysed condition of the diaphragm.

11. Faradisation of the exposed phrenic nerves in the neck, with the induced current, both in the divided and in the uninjured nerves, showed that [spastic] contraction of the diaphragm is not fatal, though Duchenne thought that it was. The cessation of respiration, and the arrest of the heart's action gradually vanish if the experiment be prolonged—when the nerves are not divided. This tetanic condition depends upon the sensory nerves. When the phrenics are divided, faradisation of the peripheral ends does not produce any of these phenomena. Duchenne probably left off too soon, or did not divide the nerves. [The exigencies of space have prevented reproduction of many of the author's arguments—for which reference must be made to the original paper.—*Ref.*]

W. BATHURST WOODMAN, M.D.

BIZZOZERO AND BOZZOLO ON PRIMARY TUMOURS OF THE DURA MATER.—In the lately published report of the observations made during 1873 in the pathological laboratory of the University of Turin, is an article by Drs. Bizzozero and Bozzolo on primary tumours of the dura mater, of which an abstract is given in the *Gazetta della Cliniche* for September 1. A review of the history of the subject has shown that a careful study of these tumours was necessary—1. To determine whether the growths described as epithelial were really such, or connective tissue tumours; 2. To determine the relation between them and growths which were undoubtedly of the connective tissue class; 3. To ascertain whether primary cancer of the dura mater really existed. The authors, having described the macroscopic and microscopic appearances observed in twenty-eight primary tumours of the dura mater, give the conclusions at which they have arrived. They are in general as follows.

Tumours of the dura mater are essentially formed of connective tissue fibres and cells. The fibres are composed of filaments, among which are found cells, either isolated or collected in concentrically stratified masses. They sometimes resemble tendinous tissue, but more frequently have the appearance of bundles of sclerosed connective tissue. The cells are rarely globular, fusiform, or stellate. There is generally a rather flattened nucleus, and the cell is reduced to a large and very

thin scale, like a [so-called] endothelial cell. The authors therefore call the cells *endothelioid*, assigning them a place between endothelial cells and flattened connective-tissue cells. Among these elements are found frequently, in various quantities, concentric globes of 'endothelioid' cells arranged in strata.

The most frequent change to which the filaments, the bundles, and the concentric globes are subject, is calcareous infiltration. In the bundles, the lime is deposited in the homogenous substance; in the fibres and globes the inorganic granules are deposited only in portions which have undergone sclerosis. In the concentric globes, the process of sclerosis consists of the deposition between the strata of cells of a homogenous substance, resembling in appearance and chemical properties that which forms the bundles of connective tissue, and separating the cells. In this are deposited the earthy salts, commencing generally from the central part of the globes. The presence of concentric globes among the connective bundles explains the occurrence of rounded calcareous concretions in the latter.

According to the manner in which the elements are arranged, three principal forms of tumours result. The tumours of the first form resemble alveolar sarcoma. The alveoli are circumscribed by trabeculae of connective tissue, variously anastomosed; they are either filled solely with 'endothelioid' cells, arranged in stratified masses, in the centre of which one or two concentric globes are not unfrequently observed; or they are filled with a few cells and many globes, some calcified, but more sclerosed. Blood-vessels enter the trabeculae. The second form of tumour resembles fasciculated sarcoma with fusiform cells. There is no regular fibrillar stroma; but there is a little connective tissue with cells sometimes containing granules of yellow pigment, sometimes surrounded by yellow gelatinous substance. Calcareous infiltration is scanty, and blood-vessels are relatively abundant. In the third form, the predominance of connective tissue, fibres and bundles, gives the growth the appearance of ordinary fibroma. Among the bundles are seen 'endothelioid,' or rather fusiform or rounded cells, with a few connective globes here and there; the supply of blood-vessels is scanty.

To the tumours of the first form, Drs. Bizzozero and Bozzolo give the name of 'alveolar endothelioid sarcoma,' and describe eight examples; those of the second form, of which they have met with three cases, they term 'fascicular endothelioid sarcoma'; and the third form, represented in five cases, is called 'endothelioid fibroma.' The authors also describe twelve cases of 'endothelioid fibro-sarcoma,' where the characters, both of fibroma and of sarcoma were exhibited in the same tumour. They discard the term 'psammonia,' for the reason that calcareous infiltration may occur in various kinds of tumour.

The paper is summed up with the following conclusions. 1. The tumours described as epithelial are based on connective tissue; that is to say, they are 'endothelioid growths.' 2. Tumours of the dura mater form a distinct and special group of connective-tissue growths (as Lebert has already pointed out). 3. There is no such a thing as true primary cancer of the dura mater; the tumours described under this name are 'endothelioid sarcomata.'

A. HENRY, M.D.

DISEASES OF CHILDREN.

VAN WYCK ON INFANTILE HYGIENE.—Dr. Van Wyck, in a paper on Infantile Hygiene (*Transactions of the Medical Society of the State of California during the years 1873 and 1874*) gives a great deal of practical advice. He says: ‘An infant is scarcely washed and dressed, ere the question is asked, “Doctor, what shall we give the baby to eat?” Really one would suppose that the helpless little being had made its *entrée* into this world in a famished condition, and not a moment was to be lost in relieving the terrible pangs of hunger, and averting impending death. Within the memory of some of us, the custom prevailed to a considerable extent of giving a dose of castor-oil a few hours after birth to the infant; and the physician who was bold enough to interdict so absurd and injurious a procedure was regarded by those compendia of infantile therapeutics and necessities, the nurse and grandmother, as knowing very little, if anything, about babies. Happily for the child, that practice seldom prevails now, but, in its stead, the less baneful, though by no means harmless, sweet-oil and anise-seed tea is suggested to clear the little one out. If to clear it out of the world is the intention, then there might be some show of reason in giving the drench.

‘On the birth of a child, the breasts of a mother rarely contain any milk, which, to my mind, is the strongest evidence that the child does not require that kind of nourishment. If such was not the case, the same provision would be made for it as for the lower mammals, for whom a bountiful supply is furnished from the maternal font at the moment of birth. There is, however, as we all know, or ought to, a viscid yellowish fluid, the colostrum, in the human breast at the period of child-birth, which not only contains all that is necessary for the nourishment of the infant until the lacteal secretion occurs, but also expedites the discharge of the meconium. An hour or two after birth, the child should be put to the breast, unless the labour has been a tedious or severe one, and the mother needs rest to recuperate her exhausted energies, when it can be deferred for six or eight hours without detriment to the child. Should the amount of colostrum not be sufficient to satisfy the demands of the infant, a little sweetened water is all that is required until the flow of milk; but should this not occur at the proper period, fresh cream diluted with boiling water in the proportion of one part of the former to ten of the latter, with the addition of a sufficient quantity of sugar of milk. It not unfrequently happens that the mother affords too little of the lacteal fluid, or it may be none at all. This truly unfortunate state of affairs is often a source of as much annoyance to the medical attendant as to the mother.

‘For twenty years I have discountenanced the use of diluted cow’s milk, substituting properly diluted and sweetened fresh cream, solely on the ground that a nearer approximation to women’s milk can be effected than in any other way known to me; and hence there is less liability to produce injurious effects.

‘Apart from this, I think there are other good reasons for using only the cream, which rises after the milk has stood some twenty-four hours. Very much of the milk sold in our cities and towns is adulterated in various ways, and in many instances

when such is not the case, the cows are improperly fed and cared for. By using the cream only, we avoid in the first instance the adulterating materials, and in the second, we are enabled to give a less quantity of a diseased or abnormal secretion.

‘Having procured a quart or more of the purest attainable milk, set aside for twenty-four hours, and then skim off, but not too closely, the cream. As the cream of cows differs in richness from a number of causes, it is impossible to give in figures the amount of water necessary for the proper dilution. I therefore direct the cream to be diluted with boiling water to an extent that will make it as near the richness of the mother’s milk at that period as possible, adding enough sugar of milk to bring it up to the natural standard of sweetness. I prefer the milk-sugar to cane or beet sugar, for the reason that, should acidification of the food occur, we have in the former lactic, whilst in the others acetic acid as a result. To be as explicit as possible, I should say that with the cream afforded from the milk ordinarily served to purchasers, the following formula will be found very nearly correct:—

| | Cream. Part. | Boiling Water. Parts. | Milk-Sugar. Parts. |
|---|-----------------|--------------------------|-----------------------|
| To a child one week old, in good health . . . | I | II | 25 |
| Two weeks old . . . | I | 10 | 25 |
| Three to four weeks old . . . | I | 8 | 25 |
| One to two months old . . . | I | 7 | 25 |
| Three to four months old . . . | I | 6 | 25 |
| Four to six months old . . . | I | 5 | 25 |
| Eight to ten months old . . . | I | 3 to 4 | 25 |

‘Should this prove too strong for the child, it will be necessary to make a further dilution with, if needed, an alkali to prevent acidification. A certain amount of lime-water is generally ordered to obviate this result; but experience has proved to me that the bicarbonate of potassa is preferable, for the reason that, as an antacid, it is equally efficacious, while it prevents the formation of so solid a curd, and thereby renders it more soluble. It should be added to the food in the proportion of one quarter of a grain to each fluid ounce, and if curd is found in the excreta, the amount should be doubled.

‘It may, and often is asked, why use the cream only? To my mind, the reason is perfectly obvious. It contains all of the salts of the milk; most, if not all the butter, while the excess of casein has been deposited or left in the residuum.

‘We are frequently called upon to prescribe for infants with whom the mother’s milk does not agree. This may arise from different causes. It may be owing to the character of secretion, or attributable to an abnormal condition of the digestive organs of the child. If to the former, either a wet nurse must be substituted, or, if that is impracticable, then artificial food must be given. Should the latter be the case, it will be necessary to dilute the mother’s milk to that degree which can be properly assimilated. Cases occur in which this fails, and it becomes necessary to feed the infant on whey, which is readily made by putting a piece of rennet in the milk, which (the whey) should be sweetened with sugar of milk. Should this prove too strong, as it sometimes does, it should be weakened with boiling water. This character of food is often objected to by both mother and nurse as not affording sufficient nourishment. But if the child does not lose weight and is doing well, why make any immediate change? As to the length of time this course should be persevered in, I say, just so long as any other food fails

to be digested. The strength of the food should be gradually increased according to the power of assimilation. We have all repeatedly had cases that taxed our best energies to find an article of diet which would agree with the infant, often failing in the best directed efforts. In extreme cases I have successfully used the expressed juice of raw or very rare beef, giving the child from one-half to two or three teaspoonfuls, more or less, *pro re natâ*; and had the whole body with the exception of the face rubbed with either sweet or cod-liver oil. The advantage of applications of oil is too obvious to dilate upon. Mothers often ask when they can change the food. My reply to this is, as long as the child is improving in strength and growth, and all the bodily functions are properly performed, and there being no other reasons for doing so, let well enough alone, and more especially so if the child is teething. A very common cause of gastric and intestinal derangement in infants is solely attributable to the ignorance of the mother, who can imagine no other cause than hunger for the fretfulness of the child, and consequently gives it the breast or the bottle whenever it cries. Regularity in feeding is as absolutely necessary for the well-being of the child as its food. A child of from one to two weeks old should not be allowed to take the breast or other food oftener than once in an hour and a half when awake, gradually increasing the time to every three hours, giving the stomach not only time to fully digest the food, but allowing a period of rest from its labour. In my opinion, as common a cause as almost any other of colic, is insufficient warmth, and in the majority of cases an examination will disclose a coldness and dampness of the child's feet and abdomen. A bottle of hot water placed at the foot of the cradle or crib will prove as great a source of comfort to the mother as the child. Much might be said on the subject of the fashion of infants' dress, and I think that physicians are not a little to blame in this matter, as their opinions on all matters pertaining to the welfare of children are respected and acted upon almost invariably by mothers, who, as a general rule, are ready and willing to make any sacrifice for, and do anything which will add to the welfare and comfort of, the "baby."

SURGERY.

LISTER ON A NEW ANTISEPTIC DRESSING.—At a meeting of the Edinburgh Medico-Chirurgical Society, on July 15 (*Edinburgh Medical Journal*, September, 1874) Professor Lister made a communication on a case of rodent ulcer, and a new antiseptic dressing suitable for such cases. The ulcer was large, on the face of a man forty years of age, and presented the characters of smoothness of the surface of the sore, with scantiness of discharge, and a definite but very narrow border of surrounding induration, free from inflammatory appearance, with painlessness, perfect general health of the patient, and absence of any affection of the lymphatic glands, although the disease had existed for eight years. The sore having been removed by the knife, presented on section an indurated base from $\frac{1}{20}$ to $\frac{1}{8}$ inch in thickness, of pink homogeneous aspect, and destitute of the ordinary appearances of epithelioma, but presenting in a well-marked form the 'prickle-cells' of Max Schultze, which indicated that, in this instance at least, the rodent ulcer was a

variety of epithelioma. As in the case of epithelioma generally, the cells presented their characters in an exaggerated form; and specimens of the 'prickle-cells' with large nuclei and interdigitating processes locking cell to cell, were exhibited under the microscope.

The disease involving a large extent of the cheek, both eyelids, both nostrils, a considerable portion of the upper lip and part of the lower one, it was impossible to cover the raw surface by a plastic operation. It was therefore of importance that efficient antiseptic means should be employed. But the antiseptic dressing usually employed, consisting of gauze impregnated with carbolic acid, and a layer of prepared oiled silk interposed to protect the raw surface from the irritation of the acid, would have been unsuitable here, because putrefaction would have spread from the mouth and nostrils beneath the 'protective,' which, while it excludes the irritation of carbolic acid, prevents in equal degree the penetration of its antiseptic virtue. In cases like the present, where causes of putrefaction cannot fail to gain access to some part of the wound, the antiseptic must be applied directly to the divided tissues, while at the same time it is desirable that it should be as little irritating as possible, so as not to interfere with cicatrization. These conditions were fulfilled very satisfactorily by means of an ointment, composed as follows:—Boric acid in fine powder one part, white wax one part, paraffin two parts, almond-oil two parts. The ingredients, after being mixed by melting the wax and paraffin, are stirred in a warm mortar till the mass thickens, and then set aside to cool, after which the firm substance is reduced in a cold mortar, in successive portions, to an uniform soft ointment. This is spread thin on fine rag, and when the almond-oil leaves it, as it soon does through capillary attraction of the porous external dressings, a smooth firm layer remains, consisting of blended wax and paraffin, together with the boric acid, which comes off from the skin without leaving any greasy substance adhering, and does not at all confine the discharge, which, while freely shed, is perpetually supplied with a sufficient quantity of the boric acid to ensure absence of putrefaction, while not preventing cicatrization. Such was the dressing employed in the present case, and it was beautiful to see the large raw surface, though involving sensitive structures, yet perfectly free from surrounding redness or puffiness, while the patient, except for a short time during the day of the operation, experienced no uneasiness whatever.

(It may not be out of place to mention here, that a still better application for cases of this kind is presented by an ointment composed like that above described, except that instead of one part of boric acid, it contains half the quantity of salicylic acid, the antiseptic virtues of which have been quite recently discovered by Professor Kolbe of Leipzig, who has also found out a method of manufacturing it cheaply.—Vide *Journal für Praktische Chemie*, 1874. Messrs. Macfarlan and Co. of Edinburgh, by slightly modifying Professor Kolbe's process, are now prepared to supply the acid in a state of perfect purity at a very moderate price. Salicylic acid, while possessing very remarkable antiseptic power, is even less irritating than boric acid.)

Dr. Chiene had found boric acid a most excellent antiseptic and deodoriser. He had used for eighteen months an ointment, consisting of one part of finely powdered boric acid to two parts of

the simple ointment of the Pharmacopœia. He had also used the boracic powder mixed, in the same proportions as in the ointment, with fuller's earth, China clay or kaolin, and starch. In superficial abrasions and excoriations, in eczematous and pruriginous eruptions, these powders were most efficacious.

Dr. G. W. Balfour found that cases of eczema, rupia, bed-sores, etc., made rapid progress under the boracic ointment, and that, in some very obstinate cases, a perfect recovery had eventually taken place.

Dr. Matthews Duncan, nearly a year ago, had been told by a patient of the very great relief she had obtained by the use of boracic-acid ointment in prurigo; since then, in many other cases, he had seen much advantage from its use.

BARBOSA ON A CASE OF REDUCTION OF DISLOCATED ELBOW-JOINT AFTER MORE THAN FOUR MONTHS.—In the *Correio Medico de Lisboa*, August 21, Dr. A. Barbosa relates the case of a lady, aged about forty, who fell on the palm of her left hand. The arm became much swollen; she did not, however, have medical advice, but treated the swelling herself, until she found that she could not bend the elbow. She then consulted Dr. Barbosa, who found that both bones of the forearm were dislocated backwards.

Four months and eleven days after the accident, Dr. Barbosa reduced the dislocation in the following manner. The patient being seated in a chair, and under the influence of chloroform, the chest and arm were fixed by straps fastened to a ring in the wall, and extension was made by means of pulleys for twenty minutes. At a signal from Dr. Barbosa, when it was judged that sufficient extension had been made, the extending force was released, and at the same moment the elbow was forcibly flexed while Dr. Barbosa guided the ends of the bones, thus reducing the dislocation. The coronoid process of the ulna was not fractured.

DERMATOLOGY.

GEBER ON A RARE FORM OF NÆVUS.—Dr. E. Geber, of Vienna, describes in the *Vierteljahresschrift für Dermatologie und Syphilis* (1874, part i.), under the title of 'A Rare Form of Nævus,' the following remarkable case.

Mathilde Z., eight years old, was the eldest child of healthy parents, living in Silesia. She was perfectly well till she was nearly two years old, when her skin became discoloured round the eyes. This gradually increased, but was regarded as rather a

blemish than a disease. The child was, however, soon afterwards attacked by catarrhal ophthalmia with photophobia, and was carried to a doctor and suffered many things at his hands for six months. Her skin was then as piebald and her eyes as bad as ever, and by the time she was four years old the patches of pigment had overspread the face, and appeared on the neck and on one hand, while her photophobia rendered her almost blind. Small tumours also appeared on the face, and rapidly increased in size and number. The parents then took Mathilde to consult Professor Hebra in Vienna, and he, 'having seen cases of the same kind and treated them without result,' advised them to abstain from active interference. Three years later the child was still worse, and a sister (of whose case we shall speak presently) being attacked with a similar disease, they were both taken to Vienna and admitted to the General Hospital. Soon after, in June 1873, when Mathilde was seven years old, Professor Billroth excised two nodules from the cheek, which were ascertained on microscopical examination to be 'sarcomatous growths.' A month later, the wounds having healed by granulation, she was transferred to Professor Hebra's department.

Her condition was then described as follows. She was small, fairly nourished, and had abundant black hair. The scalp was covered with minute patches of discoloured skin; the face was affected in the same way, the spots varying from a pin's head to a pea in size, yellow, brown, or black in colour, flat, or slightly raised, or depressed in the centre. Scattered among these were pale, shining, depressed spots and lines [answering by description to labour-marks, or to the 'linear atrophy of the skin' described by Dr. Wilks]; and here and there were seen stigmata of dilated capillaries. The skin could be easily raised, and appeared of normal consistence, and there was plenty of subcutaneous fat. Scattered over the face were numerous nodules, the smallest not bigger than millet-seeds, the largest three lines in diameter, movable, subcutaneous, painless, and firm. These tumours were confined to the face, but the piebald appearance above described extended more or less over both upper extremities and the trunk. The legs showed numerous atrophic patches, but very little of pigment or dilated capillaries. Similar vascular spots were found on the mucous membrane of the palate and cheeks, unaccompanied by deposit of pigment. The conjunctival irritation and photophobia were as bad as ever. The internal organs appeared to be healthy.

Three months later, the vascular and pigmentary spots had diminished, and the atrophic patches increased.

Perhaps the most singular feature of the case is that Mathilde's sister, Laura Z., aged five years and six months, had suffered for a year and a half from the same remarkable affection. Two other younger children were perfectly healthy. In Laura the ophthalmia, the spots of pigment, the dilated capillaries, and the atrophic patches were like those of her sister in character and in distribution. She had a single nodule on her face. The only difference between her condition and that of her sister was that her right foot was clubbed.

Microscopical examination of pieces of the skin affected with melasma, showed that the deeper layer of epidermis was full of pigment, very thick, and prolonged in the form of conical processes into the subjacent corium. The papillary layer of the

latter was full of round cells deeply stained with pigment, and there were also numerous stellate and polygonal pigment-cells, especially around the blood-vessels. The latter were much thickened, the epithelium of the inner coat being so much increased in volume that it was often observed to block up the lumen of the arteriole. Dr. Geber describes these epithelial cells as sending out processes which grew across the vessel to the opposite side, and as usually possessing from two to four nuclei. Deposit of pigment was especially abundant around the hair-follicles and the sudoriparous and sebaceous glands. The acini of the latter were swollen. The atrophic patches were shown by microscopic examination to be what clinical observation had indicated, the results of involution of the vascular pigment-spots. Here the granulation-cells of the cutis were filled with fatty molecules or had disappeared, the pigment was fading, and the whole appearance pointed, in the author's judgment, to a premature horny metamorphosis of the epithelial cells.

Dr. Geber knows of only four other cases comparable to the two he details. One is mentioned by Mr. Erasmus Wilson (*Lectures on Dermatology*, 1871, p. 97) as one of atrophy of the skin in a patient affected with carcinoma. The others (unpublished) occurred last year in Professor Hebra's wards. Two were women of low stature and dark complexion, both the subjects of cancer. The third was also an adult, and under treatment for lupus erythematosus. Unfortunately no further description of these cases is given, but it is implied that they, like Matilda and Laura Z., were affected with patches of pigment, and dilated vessels, alternating with atrophic bands.

HARDY ON HYPERIDROSIS.—The *Gazette des Hôpitaux* (no. 94) of this year publishes a clinical lecture by M. Hardy on this affection. He insists on its independence, on the one hand, of phthisis and other general diseases; and on the other, of excessive physiological sweating from exertion. Without going as far as Professor Hebra in maintaining that this (and every other cutaneous malady) should be cured as quickly as possible, without fear of 'metastasis' or other supposed mischief, the following advice would probably not be found very different in practice. 'May we not fear sick-headaches, tuberculosis, or albuminuria as the result of suppressing excessive sweat? These effects may really ensue, but they are not inevitable. If the subjects of hyperidrosis belong to scrofulous or tubercular families, or have any other hereditary taint, it is prudent to abstain from trying to relieve them. But if they be in good health, and free from inherited tendency to disease, you need not hesitate, and the cure of your patient's infirmity will not be followed by any ill results.' M. Hardy's treatment is that introduced by Hebra (vol. i. pp. 89, 90, New Sydenham Society's Trans.). He discards all internal remedies, and applies diachylon plaster so as to bring it thoroughly into contact with every part of the foot or hand, twisting strips of it round each finger or toe. This is renewed every morning, and before reapplying it the parts are well rubbed with a piece of dry flannel. After keeping the patient in bed under this treatment for ten or twelve days, the plaister is taken off, and he is allowed to go about as usual, except that the stockings should be dusted with some absorbent powder (starch, lycopodium, or asbestos) for a short time afterwards. The two cases which

follow, exemplify the results of the Vienna treatment.

A waiter in a café, aged thirty-two, perfectly well otherwise, had suffered since childhood from hyperidrosis of the feet. This had been kept at bay by lead lotions, tannin, and lycopodium; but at last, in spite of great attention to cleanliness, the affection became so severe that he could no longer walk. He then became an inmate of St. Louis. The feet were bathed in an abundant and ill-smelling sweat; the soles looked as if they had been soaked in hot water; the furrows were much deepened, and occupied at the bottom by painful fissures, which also existed between the toes. Neither the hands, the armpits, nor any other parts of the body were affected. The treatment above described was adopted, and in a fortnight he was discharged, cured, without any ill-result. He returned to his business as a coffee-house waiter, and has had no return of his troublesome and painful complaint.

The second case was that of a healthy young woman, aged twenty-one, a domestic servant. As long as she could remember, she had been the subject of continual and abundant perspiration of the hands and feet, which was not stopped even in the severest winters, though it was increased by warm weather and by movement. Her father suffered from the same infirmity, but it was limited to his feet. She had been obliged to give up needlework, and various methods of treatment had brought little or no relief. On examination, the secretion was found to be as abundant and of as evil an odour as in the last case, but there were no chaps or fissures, and she was free from pain. Hebra's treatment was first applied to the feet; and within a fortnight there was such improvement that the patient begged that her hands might be also treated. After being two months in hospital, she was so much better that she insisted upon going home, though there was still rather more secretion than normal. Three months afterwards, there was no return of the previous condition.

P. H. PYE-SMITH, M.D.

VEIEL ON THE ERUPTION PRODUCED BY BROMIDE OF POTASSIUM.—Dr. Th. Veiel, of Canstadt, publishes in the *Vierteljahresschrift für Dermatologie und Syphilis* (1874, part i.), twelve cases of this affection. After alluding to the numerous observations by Damourette and Pelvet, Sander, Voisin, and many others in England and America as well as on the continent, he narrates his own. The patients were all young (aged from fifteen to twenty-eight), and in all the eruption had the character of acne-papules and pustules, sometimes associated with comedones. It usually affected the face and scalp, but frequently the shoulders and chest, and sometimes the limbs. In one case there were troublesome boils in addition; in another (a boy of sixteen) numerous warts appeared on his face and legs. Two other patients were attacked by wheal-like erythematous patches on the legs, from a shilling to a florin in size, which were exceedingly tender from the first, soon underwent ulceration, and did not heal until the bromide was discontinued. Ordinary erythema nodosum of the lower extremities was more common, and still more so a diffused and painful dermatitis (erythema simplex), also confined to the legs, accompanied with some pyrexia, and only disappearing when the drug was omitted. Dr. Veiel has not found that the cutaneous eruption depends on any constant quantity of bromide of potassium or length of its administration,

or on the patient's age, sex, or 'constitution.' He thinks that the preference for the hairy scalp and thighs is an available point of diagnosis between it and ordinary acne; but has observed nothing distinctive in its appearance, and has failed to detect bromine in the pustules when it was abundant in the urine. [The reporter has now under his care two patients illustrating the occurrence of the bromide eruption on the scalp and face without comedones, and the furuncular form which it sometimes assumes, as first noticed by Voisin in 1868.—*Rep.*]

OPHTHALMOLOGY AND OTOLOGY.

WREDEN ON A CASE OF PHLEBITIS OF THE SINUSES OF THE DURA MATER, CAUSED BY OTITIS.—In the *Archives of Ophthalmology and Otolaryngology*, vol. iv. no. 1, Dr. Wreden gives the history of, and remarks on, an important case of phlebitis, ending in recovery so complete, that there is no trace of any functional injury. A boy, aged fifteen, of scrofulous diathesis, who had previously suffered from inflammations of the ear, was placed under his care on account of acute otitis media, with implication of the mastoid portion of the temporal bone. While progressing favourably, the boy became one day intoxicated, the effects of which were irritation and distension of the cerebral vessels and phlebitis of the transverse sinus. The course of the phlebitis was as follows. The first symptoms referable to affection of the lateral sinus were noticed on November 27, and under treatment disappeared so rapidly, that on December 1 following, the patient insisted on driving with his mother to a railway station, from which she was about to make a journey. Twenty-four hours after this drive (December 2), the inflammation of the cerebral sinuses returned with increased violence, and spread, on December 3, downwards to the right internal jugular vein; on the 4th, upwards to the superior longitudinal sinus; on the 5th, to the left lateral sinus and the left internal jugular vein; and on the 7th, to the right cavernous sinus. Dr. Wreden's method of tracing the course of the affection to these different parts is worthy of note. The oedema was confined to the skin of the region of the ear as long as the transverse sinus alone was implicated; but when the internal jugular vein of that side became affected, the phlegmasia alba dolens extended from the mastoid process downwards over the side of the neck to the clavicle, the most painful point on pressure, and the most swollen part, corresponding to the course of the internal jugular vein. On the 3rd, puffiness of the face accompanied phlebitis of the internal jugular, which passed to 'great oedema' of the right side of the face when the large branches of the right facial became affected on the 4th; while, on the extension of the facial phlebitis to the smallest branches of the veins of the cheek, erysipelas bullosum of that region occurred, the extension to the capillaries of the forehead being accompanied by the same affection there. On December 7, there were symptoms of irritation and checked circulation in the right eye, showing the implication of the right cavernous sinus. Dr. Wreden considers the characteristic sign of thrombosis of the internal jugular vein to be a dilatation of the external jugular vein, with a distinctly visible

increase or diminution in fulness corresponding to inspiration and expiration. It is dependent on collateral blocking of the circulation, and is usually a temporary phenomenon. The thrombosis of the internal jugular vein was also marked by clonic and tonic spasms of the sterno-cleido-mastoid and trapezius muscles due to irritation of the spinal accessory nerve from the thrombosis of the sinus of the vein while passing together through the jugular foramen. Repeated violent bleedings from the nose and epileptiform convulsions marked the implication of the superior longitudinal sinus, the former being due to back-pressure on the nasal veins, and the latter 'to capillary hæmorrhages in the cortical substance of the convexity of both posterior cerebral lobes.' Wreden points out that, in all the recorded cases of thrombosis of the upper sinus, those individuals who presented after death these lesions of the gray substance were subject to epileptiform attacks during life. Paralysis of the abducent nerve, unilateral headache, epiphora, photophobia, ptosis, oedema of the eyelids and conjunctiva, and weakening of the power of vision, showed affections of the cavernous sinus, and consequent irritation of the sixth, fifth, and third nerves, and intra-ocular venous congestion by mechanical hyperæmia.

In the course of the paper the author makes a few well-placed remarks on the terms 'thrombosis' and 'phlebitis.' He thinks the term thrombosis ought to be applied to those cases which owe their origin to mechanical influences, such as a diminution of the propelling power of the heart, impeded expansion of the lungs and consequently back-pressure on the sinus, compression of the sinus, or coagulation in afferent or efferent veins, and extension of the coagulation to the sinus, unaccompanied by fever or pyæmic symptoms; while the term 'phlebitis' he would limit to inflammatory processes of the sinuses, propagated from parts in the vicinity, by direct traumatic injury, or from the transference of the process from large veins communicating with it, and accompanied by violent fever and often giving rise to pyæmic or septicæmic symptoms. W. LAIDLAW PURVES.

MISCELLANY.

PRIZES.—The Royal Lombardian Institute of Science and Literature announces the following prizes for competition:—*Cagnola prizes* (ordinary)—1. For 1875: Transfusion of blood in man. 2. For 1876: Electrotherapy applied to the resolution of tumours; each prize consists of 1,500 lire (60*l.*) and a gold medal of the value of 20*l.* 3. For 1876: Drunkenness in Italy as compared with other countries; prize, 2,000 lire (80*l.*) and a gold medal of the value of 20*l.* *Cagnola prizes* (extraordinary) for 1875:—1. The nature of miasmata and contagia. 2. The direction of balloons. 3. The method of preventing the counterfeiting of writing; each prize consists of 1,500 lire, and a gold medal value 500 lire. *Secco Commemo prizes*, each 864 lire (about 34*l.* 11*s.*). For 1875: Determination of the action of luminous rays of different colours on vegetation and on animal nutrition; determination of the best antifermentatives and antiseptics, and the best disinfectants and deodorants, whether single or compound. For 1877: Indications of the best method of cremation as a substitute for inhumation. *Castiglioni prize* (extraordinary), 600 lire (24*l.*): To point out whether, as a prophylaxis against small-pox, preference should be given to animal or to humanised vaccination. The essays in competition for each of the above-mentioned prizes must be sent in on or before the last day of February in the respective

years. *Fossati* prizes, each 2,000 lire (80%). For 1875: The history of the progress of the anatomy and physiology of the cerebrum in the present age, with special reference to *Gall's* doctrine. For 1877: Experimental clinic and pathology of the cerebellum, with reference to the functions assigned to it by the doctrine of *Gall*. The essays must be sent in by April 1. Foreigners as well as Italians (except actual members of the Royal Institute), may compete for any of these prizes. Essays must be written in either the Italian, French, or Latin languages, and must be sent post-free within the time specified to the secretary of the institute, at the Brera Palace, Milan; they must be anonymous, and signed with a motto, the name of the author being communicated in a closed envelope. Competitors are recommended to state distinctly for which of the prizes they are candidates. The prizes will be conferred at a public meeting on August 7 next following the closure of the competition.

SPONTANEOUS COMBUSTION.—The vexed question of the possibility of spontaneous combustion has again been lately discussed before the Paris Société de Chirurgie, in a paper by M. Chassagniol of Brest. The author stated that spontaneous combustion was first mentioned in 1692, since which time it had found a certain number of partisans in France. The Germans, however, with M. Casper at their head, entirely deny its possibility. M. de Chassagniol has endeavoured to sift the truth from the conflicting accounts on record, and has, for this purpose, tried to find some authentic facts. He has not, however, been able to do so in any scientific records; no medical man, no person of authority has ever been present at a case of spontaneous combustion of the human body. Many authors have affirmed that the human body burned on these occasions with a blue flame, and diffused an empyreumatic smell, but these characteristics are met with in many kinds of combustion. Instances have been sought for in alcohol-drinkers, especially amongst women, but hitherto without success. It is really a question whether the possibility of spontaneous combustion of the human body can be theoretically demonstrated. The original idea was that the alcohol in drinkers took fire. Dead bodies, or portions of dead bodies, however, burn but very slowly, even after having been steeped in alcohol for some days. After having injected alcohol into the veins of dogs, it was found impossible to obtain combustion of these animals; electric combustion was then tried, and finally, the presence in the human body of a gas which would either light up spontaneously, or on a light being brought near to it, was sought for. Numerous analyses have not been able to show the presence of sulphuretted hydrogen in the different parts of the human body. In later times it has been a question if a resemblance could not be found between the spontaneous combustion of stacks of hay and straw, and that of the human body, but there is really no analogy between them. M. Chassagniol is, therefore, necessarily brought to the conclusion that the fact of spontaneous combustion is not made out; and M. Horteloup, who read his paper for him before the Société de Chirurgie, strongly doubts if any case of spontaneous combustion in the human subject worthy of serious attention has ever been brought under notice.

DR. KLEIN'S RESEARCHES ON THE TYPHOID GERM. The interesting observations of Dr. Klein on the subject, to which Professor Tyndall has prominently directed public attention, have been briefly summarised recently in the *Medical Times and Gazette*. Sections of the hardened ileum of typhoid patients show, according to him, that an active absorption of peculiar organisms goes on in the mucous membrane over, and especially around, the Peyer's patches. These organisms are carried thence into the lymph-canals and the venules of the mucous membrane. In the earliest case which he examined, where death had occurred on the seventh day after the first appearance of headache, the crypts of Lieberkühn were found to contain peculiar greenish-brown spheroidal corpuscles of very

variable size, the largest being twice or three times as big as a human red blood-corpuscle, and the small ones only half or a quarter as large. Where these bodies lie closely grouped together, as is generally the case, they appear of a dark olive-green colour; and the corpuscles at the edge of such masses, or where they are completely isolated, exhibit transitional forms, due to incomplete subdivision. Similar corpuscles are found in the tissue of the mucous membrane, where they appear to be contained in the lymphoid cells of the adenoid tissue. The minute veins, and also some of the lymphatic vessels, contain large numbers of them, and in the former they subdivide rapidly, so as to form greenish-yellow granular micrococci, arranged in groups of two or four, as well as in rings and other figures. The micrococci have their origin in a mycelium whose filaments are branched and apparently smooth, and of a greenish-yellow colour. These organisms occur not only in the neighbourhood of Peyer's patches, which are moderately swollen, but also in parts of the mucous membrane which to the naked eye show no alteration except slight general swelling, although microscopically the follicles of the patches in one case were found to have undergone the following changes. The central part of the follicle, especially where it lies in the submucous tissue, was converted into a spongy substance by the formation of spaces around its blood-vessels, their wall consisting of the adenoid tissue with which the latter are sheathed. The lymphoid cells of this tissue were converted into large granular bodies containing two to five, or even more nuclei, which greatly resembled the nuclei of endothelial cells. In several of the follicles true giant-cells were seen. In a later stage (twelfth day) the mucous membrane itself showed somewhat similar changes, and the multinuclear lymphoid cells were found in its venules and in those of the submucous tissue, as well as in the lymphatics of the latter. Dr. Klein is unable at present to give a decided opinion whether the above alterations are directly dependent on the presence of the micrococci, or whether they must be considered as secondary to changes in the vascular system. The passage of micrococci inwards from the free surface of the intestine can be traced through the epithelium into the substance of the mucous membrane, and especially towards the crypts of Lieberkühn; and this occurs in parts which are at some distance from the swollen Peyer's patches, and which appear nearly or quite unaltered to the naked eye.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17s. 4d.; free by post, 19s. 6d.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & CO., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre.—Leipzig: Mr. K. F. KOEHLER.—Florence: Mr. E. LOESCHER.—Brussels: Mr. C. MUQUARDT.

The First Volume, containing upwards of Two Thousand Articles abstracted and compiled by a staff of Fifty Hospital Surgeons and Physicians, is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for the year 1873 are also ready, price 1s. 6d. each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & CO.—Calcutta: THACKER, SPINK & CO.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & CO.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & CO., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S.W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, NOVEMBER 18, 1874.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

HAMMOND ON THE EFFECTS OF ALCOHOL ON THE NERVOUS SYSTEM.

The New York *Psychological and Medico-Legal Journal* has long been published under the name of the *Psychological Journal* simply, but as in the new series it is intended to give more attention to medico-legal subjects, the title has been altered. The first number contains an inaugural address, delivered by Dr. William Hammond as president of the New York Neurological Society, on the effects of alcohol on the nervous system. He maintains that the action of alcohol in small quantities retards the destruction of tissue and supplies material for the generation of force. One of the products of tissue-metamorphosis is carbonic acid. Many years ago, Dr. Prout ascertained that after the use of alcohol the amount of carbonic acid excreted by the lungs was considerably reduced. Within the last few years other investigators have arrived at the same conclusion, and have extended their inquiries to the other excretions of the system. Thus Böcker ascertained that under the use of alcohol there was a very decided diminution in the quantity of the urine eliminated, and in the amount of its solid constituents.

Desirous of ascertaining the facts for himself, Dr. Hammond instituted a series of experiments calculated to determine the real value of alcohol as an aliment or a substitute for aliment. These experiments were performed on himself, and consisted of three series: 1st, the influence of alcohol when the food was just sufficient for the wants of the organism; 2nd, when it was not sufficient; 3rd, when it was more than sufficient.

Four drachms of alcohol, diluted with an equal quantity of water, were taken at each meal. Dr. Hammond not being an habitual drinker of alcoholic liquors in any form, the experiments were not open to the objection that they were performed upon a person hardened to the use of intoxicating beverages. During the first series, when the food was such as to maintain the weight of the body at its normal standard, it was found as the result of experiments, continued for five days, during which time sixty drachms of alcohol had been taken, that the weight of the body had increased from 226.40 pounds to 226.85 pounds. In the same period the amount of carbonic acid and aqueous vapour exhaled from the lungs had undergone diminution, as had likewise the quantity of urine and its solid constituents. While these experiments lasted, the general health was somewhat disturbed; the pulse was increased to an average of 90 per minute, and was fuller and stronger than usual, and there was an indisposition to exertion of any kind.

The inference to be drawn from these experiments

is that, when the system is supplied with an abundance of food, and when there are no special circumstances existing which render the use of alcohol advisable, its employment as a beverage is not to be commended.

In the second series of investigations, the food was such as to cause an average decrease in the weight of the body of .28 of a pound daily. Under the use of the alcohol not only was this last overcome, but there was an average increase of .03 of a pound daily. The effects on the excretions were similar to those which ensued in the course of the experiments of the first series. But, unlike the first series, no abnormal results were produced in the general working of the organism. It is in similar cases, therefore, that the proper use of alcohol is to be commended; that is, when the quantity of food is not such as to allow the due performance of such physical or mental labour as may be necessary; or what amounts to the same thing, when the digestive or assimilative functions are not so efficiently performed as to cause the digestion and appropriation of a sufficient quantity of food ingested to meet the requirements of the system.

In the third set of experiments, in which more food was taken than was necessary, the ill effects of the alcohol were well marked. Headache was constantly present, the sleep was disturbed, the pulse was increased in frequency and force, and there was a general feeling of *malaise*. Notwithstanding all these abnormal phenomena, the body continued to increase in weight above the ratio which existed before the alcohol was taken, and the excretions were diminished in quantity.

'After such results,' says the experimenter, 'are we not justified in regarding alcohol as food? Alcohol retards the destruction of tissue; food supplies the material for new tissue. Now, as alcohol stops the full tide of this decay, it is very evident that it must furnish the force which is developed under its use, but how it does so is not clear. Lallemand, Perrin, and Duroy contend that it is excreted from the system unaltered. If this were true of all the alcohol ingested, its action would be limited to its effects upon the nervous system, produced by actual contact with the nervous tissues; but there is no more reason to suppose that all the alcohol taken into the system is thus excreted, than there is for supposing that all the carbon taken in food is excreted from the skin and lungs as carbonic acid. It is not at all improbable that alcohol itself furnishes the force directly, by entering into combination with the first products of tissue-decay, whereby they are again assimilated, without being excreted as urea, uric acid, etc. Many of these bodies are highly nitrogenous, and under certain circumstances might yield their nitrogen to the construction of new tissues. Upon this hypothesis, and upon this alone, so far as I can perceive, can be reconciled the facts that an increase of force and a diminution of the products of the decay of tissue attend upon the ingestion of alcohol.'

J. LOCKHART CLARKE, M.D.

BRAUN-FERNWALD ON ARRESTED DEVELOPMENT OF THE UTERUS, VAGINA, AND VESTIBULUM.

In the *Wiener Medizinische Wochenschrift* for September 5 and 12, 1874, Professor Braun-Fernwald has an interesting article on this subject.

1. The absence of the uterus in fully grown women is generally combined with deficiency of the entire vagina, but with perfect development of the vestibulum, the mammae, and of the mons Veneris. It is by no means a rare accident, the writer having seen no fewer than eleven cases. The genitals in these cases terminate in a *cul-de-sac* at the hymen; the vestibulum presents a pouch about the size of a thimble; the most careful bimanual examination *per rectum* can either discover no signs of an uterus or vagina, or occasionally a filbert-sized rudiment; the menstrual molimen is absent. The patients seek medical aid, as a rule, for *impotentia cœundi*, sterility, or an uncontrollable dribbling away of urine. Some years ago he met with three persons labouring under urinary fistulæ, with absence of the vagina and uterus, with an opening into the bladder an inch wide, arising from rupture of the urethra through violent coitus. They were cured by paring the edges and bringing the raw surfaces together by silk sutures. It is impossible to make a vagina in this affection. Every attempt to do so by making a free space between the bladder and rectum with the finger failed, through inability of keeping the parts separate, and preventing them from uniting again.

2. The arrest of the growth of the uterus is either congenital or acquired, its seat being indicated by a muscular or fibrous structure. The vagina ends in a *cul-de-sac* or communicates with a rudimentary uterus, whose shape may be various, round, smooth, and arched, generally, however, composed of two horns, which are either solid or hollow bodies, about the size of a millet-seed or pea, and lined with mucous membrane (*Uterus bipartitus* of Mayer and Rokitsky). The external genitals are, as a rule, regular in form; the ovaries are normal or abnormal. Connection may take place by the vagina or by the usually patulous urethra. Through closure of the uterine opening of the Fallopian tubes, a tubohæmatocœle may happen. The sterility that occurs is always incurable.

The *Uterus fetalis seu infantilis* arises from some disturbance in the continuous development of the organ. Its cervix may be from one to two inches long; the body, however, is always very short, about the size of a hazel-nut, with very thin walls. The infravaginal portion of the cervix may be a mere rudiment, or very short, with exceedingly small external but wide internal os. It is quite the exception for the vagina to be of normal width. The tubes are usually perfectly well formed; the ovaries, however, are absent or very small; the Graafian vesicles are absent, or the contained ova do not arrive at maturity. Menstruation is either entirely deficient, or is seldom, irregular, scanty, and more or less painful. Coitus is possible, but sterility is incurable. From the walls of the fetal or infantile uterus being so thin, it is also styled *Uterus membranaceus*, and from its coming on in young persons after delivery, *Atrophia uteri præcox*. Dr. Braun-Fernwald has repeatedly seen, with procreation at the eighteenth year, incurable amenorrhœa and sterility proceed from this degeneration of the uterus. At puberty the growth of the uterus is also left behind, without, however, retaining its infantile form; it is throughout small (*uterus parvus*) both body and cervix, also the infravaginal portions are deficiently developed. This defect exists with perfect development of the ovaries, vagina, and breasts; at times it is attributable to constitutional disorders. Menstruation is not always absent; an *uterus parvus* may conceive, and bear at

the full time. The rudimentary or small uterus is diagnosed by vaginal or rectal examination, by measurement of the uterus by the uterine sound, or by passing a catheter into the bladder at the same time that the fore-finger is introduced *per rectum*. Amenorrhœa proceeding from this cause is generally not cured by emmenagogues, the uterine douche, or electricity. Only in slight deviations from the normal does menstruation at times follow these medications. The writer has seen even in *uterus parvus*, without any medication whatever, menstruation occur with an universal and vigorous development of its body.

3. In *Uterus duplex et unicornis*, defective growth of the female generative organs proceeds mostly from abnormal changes of Müller's ducts in embryonic life, which, as is known, through unfolding and fusion of their contiguous surfaces form the vagina, the uterus, and the Fallopian tubes. Hence it arises that a remarkable reciprocal harmony is not unfrequently found to exist between the several defective developments of these structures, whereas the malformations of the ovaries and of the external genitals which do not arise from Müller's ducts, repeatedly differ. Pregnancy can only occur in partial obliteration of Müller's ducts, with free communication to the ovaries. According to the degree of the defect in development gestation is either prematurely with much danger interrupted, or terminates physiologically at full time, or produces various disturbances.

a. *Uterus duplex separatus, seu Uterus didelphys* (Kussmaul, Klob) is described as an arrest of development, where on each side an uterus unicornis exists, tolerably separated from each other, with a vagina imperfectly developed, or, when met with, usually bipartite. Uterus didelphys occurs only in children incapable of an independent existence. It is not a real reduplication, but a division through the keeping asunder of the dual components of this organ. If the fusion of the middle section of Müller's ducts do not proceed in the normal way, an *Uterus bicornis* or *bilocularis* will be produced. The uterine cavities in this instance either reach from the fundus to the vaginal orifice as two distinct channels, or are split up into two or mere cavities by a short membranous partition. Each cavity has one Fallopian tube and one ovary. The mere width of the opening between the two uterine cavities does not serve to distinguish an uterus bicornis from a bilocularis, but only the clearly demonstrable or imperceptible separation of the upper surface of the uterus.

b. The extreme degree of *Uterus bicornis*, that is, where from a defect in the blending together the two horns with a double vaginal portion open into a single or double vagina, occurs very rarely. Formerly, a deep sulcus between the two horns was falsely described as constituting a double uterus, but a uterus bicornis never has two ovaries or two Fallopian tubes to each cavity.

Kussmaul distinguishes two forms of uterus bicornis, according as the separation of the uterus into its two halves by means of a conjoint partition-wall, which extends downwards from the point of junction of two diverging horns, is complete (*uterus bicornis duplex*) or not (*uterus bicornis infra simplex seu semiduplex, seu unicollis*). The bicornate uterus always distinguishes itself from the uterus didelphys by the two uterine halves appearing always externally, or at least in the lower section, more or less united and blended together, whereas in uterus didelphys they are completely separated and apart.

The isthmus between the two horns is horizontal; beneath it the uterine horns unite together (Rokitansky). The vaginal portion of the uterus bicornis duplex is either single; the septum dividing its cavity, from being thin, becoming thicker and stronger as it ascends; or each horn possesses its own vaginal portion. Should one horn become impregnated it enlarges, and its walls correspond in thickness to the usual gravid uterus. The pregnant horn rises up into the abdominal cavity, and both retain their same relative position in their proportional growth as they did when unimpregnated. Should the fecund horn be the more developed, it ascends perpendicularly upwards into the abdominal cavity, and the empty one hangs at its side below it.

Professor Braun relates an interesting case, where a pregnant woman had a tumour about the size of a fist in Douglas's pouch; the vagina was narrow and the os pushed upwards and forwards. The great elasticity and the changeable consistence of this tumour caused a connection between it and the uterus to be suspected. To make certain, the finger was pushed up about one centimètre above the external os, and in passing backwards came upon an opening about one centimètre wide, into which the finger could be inserted to about the distance of four centimètres, and the decidual membrane could be made out; it was, in fact, an empty horn prolapsed beneath the os of the pregnant one. It was reduced, and the patient went her full time and accomplished a normal puerperium. If the less developed horn become pregnant, it passes obliquely up into the abdomen, and the empty horn has in this case occasionally a perpendicular position. In the five cases observed by himself of uterus bicornis there was never twins, nor was extraction required; all the children were born living, and the puerperium ran a normal course.

Rupture of the uterus or habitual abortion has never been observed by Professor Braun-Fernwald; but this has not been the case with Rokitansky.

In uterus bicornis unicollis, pregnancy and birth have, as a rule, no disturbing influence.

Habitual shoulder-presentations only at times occur, when, and in those instances where, the less deeply the septum descends upon the internal os, the wider and shorter the uterus becomes, and the shallower the sulcus of the fundus is made out through the abdominal walls. He performed turning three times in a case of uterus bicornis unicollis for shoulder-presentation; the last was fatal; the necropsy showed the cause.

c. The unhorned partite uterus, the *Uterus bilocularis* of Rokitansky, *Uterus septus* of Kussmaul, consists in a division of the cavity of an externally single uterus by means of a more or less deep descending perpendicular septum springing from a normal fundus uteri.

When the septum is complete throughout the whole length of the uterus, Kussmaul calls it *Uterus septus duplex*; when incomplete, *Uterus subseptus*. In isolated cases the vagina is also divided by a continuation of the uterine septum, descending more or less low down its cavity.

As a rule the vagina is single; conception, gestation, and parturition are possible, and are generally attended with no particular disturbances.

Out of the eight cases of delivery with uterus bilocularis observed by the author, he only finds three instances worthy of special notice; the first, when with uterus septus duplex and vagina duplex there

was sterility, which was not removable by splitting up the septum to the uterine cavity; the second in which three normal deliveries took place with perfect preservation of the vaginal septum; and the third, where in a premature breech-case the cervix of the empty half was patulous and penetrable for some distance, and the vagina wide and large, whereas the vaginal half that led to the gravid loculus was small and contracted. The septum was stretched over the presenting part of the fœtus like a veil.

d. The *Uterus unicornis* consists of one horn only, the second arrested horn being attached to it, or entirely absent. It presents a long cylindrical spindle-shaped, curved lank body stretching towards its corresponding side, and terminating gradually in a point, disappearing in the Fallopian tube, on which a normal ovary hangs in the usual way. Its cervix is always very small. Pregnancy may occur with this abnormality, and terminate normally. The accessory horn may be impregnated through the migration of an ovum, but it ends in rupture.

In atresia of one of the mouths of the womb, both in uterus and in vagina duplex, hæmatometra and hæmatocolpos may occur in the imperforate horn. An unilateral hæmatometra in uterus bicornis was observed by Leroy; the attention of physicians was attracted to it by Rokitansky; but it was proved by Schröder, that some cases described as hæmatocele anteuterina were referable to atresia with duplication of the vagina.

As in uterus duplex without atresia, so also here the two uterine halves can act separately in menstruation; either both sides may be the seat of hæmorrhage, or only one. If menstruation occur only in the closed half, the recognition of hæmatometra is facilitated by the apparently existing amenorrhœa. If the menstrual flux occur in both halves, it is very easy to be deceived by the unarrested flow of blood from the patent cavity. Through the retention of blood in the closed cavity a tumour is formed, which lies to the side of the vagina of the freely discharging horn, and at its lower extremity bulging into the vagina. The patent horn of the uterus bicornis is not in apposition along its whole length with the tumour, but at its upper end is deflected from it.

The intimate connection of the tumour with the uterus, shown by palpation and the sound, prevents it from being confounded with an ovarian cyst. Later on, the tumour may perforate the other uterine half (Veit).

More frequently hæmatocolpos lateralis occurs in a bipartite vagina, of which Veit has made three very instructive observations, and has depicted it in the following manner. 'A fluctuating swelling presented itself on the side of the vagina; the cervix had a fixed wall-like position; the vault of the vagina existed only on one side; the os had a horseshoe opening or a slit running from before backwards; the tumour was livid or pale red, projected into the open entrance of the vagina, occupied not only one side of it, but extended as far as the anterior half of the vestibulum; there were also dysmenorrhœa and retention of urine present.' Dr. Braun-Fernwald has seen a case of hæmatocolpos and vagina duplex in a woman at two confinements, which caused an obstruction to delivery, and had to be removed by puncture through the septum.

Cases of pyometra and pyokolpos, as also hydro-metra lateralis, as consequence of congenital closure of a rudimentary vagina in uterus duplex, have been

published by Breisky, and over twenty cases of hæmatometra, and hæmatokolpos by Rokitansky, Credé, Herzfelder, Hegar, Thügel, C. Braun, Beronius, Simon, Breslau, Olshausen, Holst, Jones, Churchill, Schröder, Passauer, Neugebauer, and Freund.

To diagnose uterus and vagina duplex, complicated with hæmatometra, Simon's method of high rectal exploration suits admirably.

Hæmatometra in uterus bicornis, with a rudimentary horn, has not, as yet, been described either anatomically or on the living subject. Hegar has, however, recently made public two most instructive observations, in which a swelling with a firm elliptical pedicle arose from the isthmus uteri, and on puncturing it coffee-coloured blood could be drawn off.

The lowest grade at which defective blending of Müller's ducts can arrive are the membranous bands occasionally met with in the dome of the vagina, more rarely in the cervix alone, in the middle of the vagina, under the name of a duplicate hymen, still more frequently, however, as hymen bifenestratus.

In all cases of defective development, menstruation occurs simultaneously in both halves. The hypertrophied substance of the uterus, the effect of pregnancy, expands in the direction of the septum. They terminate usually in simple pregnancy. When an ovum develops in a well-formed horn it often arrives at a regular delivery at full time; when the growth, however, of the uterine tissue is deficient, it occasions abortion, premature labour, feeble pains, false presentations, and in exceptional cases spontaneous rupture of the uterus.

Atresia vulvæ seu labialis, consists either of adhesion of the posterior two-thirds of the labia majora, or of a genuine abnormal lengthening of the perinæum, in which impregnation may occur with an imperforate hymen.

The latest explanation propounded by Wernich and Fehling respecting the mode in which conception takes place in stenosis of the vagina, or of the vestibulum, is that in cohabitation an erection of the lower section of the uterus occurs, which is coupled with an ejection of the cervical fluid similar to that of the penis. They support this view on the apparent phenomenon of erection experienced by the examining finger, the cervix becoming hard and firm to the touch; still further, Rouget and Henle have in fact verified the erectile apparatus, which exhibits great similarity with that of the vagina and of the ovary. At the moment of the greatest excitation an ejection of the cervical fluid takes place, and in the act of relaxation the deposited fluid in the vagina is immediately sucked up.

In cohabitation, conformably with experience, an erection and momentary depression of the uterus happens; it can be still more distinctly observed during the process of expulsion of the placenta.

Where impregnation is effected with imperforate hymen, its rationale is as follows. The cervix descends on a level with the aperture in the hymen, the cervical fluid is ejected into the opening, intermixed with the semen deposited on the vestibulum; the spermatozoa, during the relaxation of the cervix, are in the backward flow of the cervical fluid drawn up into the uterine cavity. In an article of the author's, in the *Medizinische Wochenschrift*, he has still more nearly, from personal observation, proved this to be a fact.

The diagnosis of the above-named conditions of the uterus is generally very difficult, and at times im-

possible. An uterus bicornis may be either ascertained by aid of palpation and percussion of the abdomen, or may be suspected when there are bipartite vagina, a double cervix, abnormal tumours, and the sudden appearance of internal hæmorrhage. The uterine sound should never be passed in the gravid uterus to aid a diagnosis.

The treatment should not be directed to the condition, but emergencies should be dealt with as they arise on the usual established rules. Whenever any membranous bands or the septum of a double vagina impede delivery, they should be slit up with the scissors; the hæmorrhage, if any, is either arrested by the advancing fœtus, by cold applications, or a tampon.

W. C. GRIGG, M.D.

ON THE TREATMENT BY MINERAL WATERS OF CHRONIC DISEASES, AND ON THE PRINCIPAL SOURCES ADAPTED TO THE VARIOUS MORBID CONDITIONS. BY M. GUBLER.*

(Concluded from page 710.)

XV. The Treatment of Syphilis.

Waters render various services in cases of syphilis. Sometimes they are a test which makes the diagnosis positive; sometimes they attack directly the morbid symptoms; at other times they contribute to restore a constitution broken down by the poison. Where there is a doubt as to whether symptoms are referable to syphilis, or where even in the absence of symptoms there is a suspicion of a taint of it, certain mineral waters are made use of as a sort of touchstone, in order to bring out an eruptive *poussée*, which will end in an eruption characteristic of the disease. Aix-les-Bains and Luchon are the places most resorted to for this purpose, but any hot sulphur-waters will answer.

It has been said that sulphur-waters, without impeding the effects of the concurrent use of mercury, prevent any disagreeable consequences of its use, and therefore it is common to employ the two together. I do not share the illusions of some distinguished physicians on this head, and I believe that, if the waters prevent the disagreeable results of mercury, they at the same time counteract its beneficial and curative action. The restorative waters are the ones more rationally indicated in syphilitic cachexia, which has succeeded the secondary and tertiary stages of the malady. In such cases pure iron waters, or some with chloride of sodium, or sea-water itself, will do much to restore health. Are there any waters really curative of syphilitic conditions? The thing is not impossible, but there has been as yet no satisfactory demonstration of the fact. Aulus in Ariège has long had a special reputation in these cases, and boasts of many cures. I wish there were detailed accounts of them. A recent analysis of the waters of Aulus by a skilful hydrologist, Dr. Garrigou, may account for this, as he has discovered in it a minute quantity of chromium, a remedy of late recommended in the treatment of syphilis.

[M. Gubler's views on the treatment of syphilis are much less sanguine than the ordinary ones, which have recently been explained at some length by Dr. Reumont. (See LONDON MEDICAL RECORD, June 10.) I fear that the traces of chromium at Aulus will not inspire much confidence.—Tr.]

* *Journal de Thérapeutique*, no. 10 et seq.

XVI. *Treatment of Intermittent Fever and of Paludal Cachexia.*

No mineral water is of use in arresting paroxysms of marsh-fever. The use of arsenic in fever is very limited, and even Bourboule does not contain it in sufficient quantity to be of use in such cases. But, on the other hand, many waters are well adapted for removing the sequelæ of malarious poisoning. Encausse and Campagne (warm, the first containing sulphate of lime, the last indifferent) contrary to what might be expected from their composition, boast of dispersing these sequelæ; but other waters claim to do so more effectively, in right both of experience and of theory. At the head of these come the iron waters, gaseous or not; and the complete saline ones of volcanic districts. Forges, Spa, Cassuejols of the first class; Chateauneuf, Royat, Saint-Mart, Saint-Nectaire of the second.

The arsenical waters are also useful, especially when they contain a sufficient quantity of the salts wanted for the blood. In this point of view Bourboule occupies an important place, as also most of the other less arsenical waters of Auvergne. Next to them come the alkaline iron waters of Boulou, Neyrac, Marcols, etc., and the chloride of sodium waters of Bourbonne, Salins, Uriage, along with an immense number of salt waters, which can be made use of in marsh cachexy.

[It is obvious that waters of these classes are abundant in other countries; Bourboule, owing to its unusually large amount of arsenic, being the only exception.—*Tr.*]

XVII. *Treatment of Surgical Affections.*

This subject has already been indirectly touched on, under the head of chloride of sodium and of indifferent waters, as we have seen that prolonged baths at Nérès cause a considerable relaxation of old cicatrices and of old thickenings, the result of inflammation whether caused by burns or by gouty or rheumatic attacks—and that the stimulant chloride of sodium and sulphur waters resolve inflammatory congestions, from which ankyloses, white swellings, and other lesions result. Whether these lesions have been occasioned by constitutional causes or by violence, such as blows and wounds, they can be successfully operated on by the waters of Aix-les-Bains, Gréoulx, Ax, Luchon, and Barèges, or of the two Salins, Salies, Bourbonne, Balaruc, Bourbon, or Chateauneuf, Saint-Nectaire, etc., or by hot sea baths, with or without the addition of sea-weed.

Resolving treatment may, strictly speaking, be confined to the use of hot thermal waters, without reference to their mineralisation. But the stimulant effects of a highly mineralised water are required, when it is wished to produce general excitement, to cause a flow towards the seat of a cold engorgement, which it is desirable to stir up, either with the view of producing more active resolution, or of setting up inflammatory action, which will aid the separation of bone, or the extraction of bullets or of foreign bodies. Bourbonne, Bagnères, and Gréoulx are the best for such purposes.

These powerful waters are, however, contraindicated in the cure of traumatic lesions of the viscera, when there are anal fistulas or hæmorrhoids, in subjects inclined to sanguineous congestion, or to hæmorrhages, or to inflammation of the bowels—and in all who have cerebral or cardiac affections.

Many retractions and deformities of limbs and

false ankyloses yield to prolonged *illutatio*n, without the aid of very high temperature, for instance at Barbotan, Dax, or Saint-Amand.

XVIII. *On Parallel Corrective or Auxiliary Treatment.*

With surgical affections we have concluded the list of maladies suited for mineral-water treatment. But hitherto I have only indicated one cure and one water for each category of diseased action, taken in the abstract, as if the morbid condition were in its nature fixed and invariable, and required always and only the same water, at least during the appropriate season for its use. But chronic diseases often change nearly as rapidly as acute ones; sometimes the aspect of things alters completely from week to week in the tuberculous or the rheumatic; and therefore it may be only rational, to vary the mineral water employed, according to the variation of the symptoms.

Besides, the cases for which we prescribe waters, are by no means simple. The principal malady is almost always complicated, either with other lesions, or with diathetic causes, or with prevailing or consecutive disturbance of the general health. Such circumstances necessarily demand the simultaneous use of varied mineral-water treatment.

Further, mineral waters are not such entirely harmless agents as never to injure by excess of their physiological action; this should be guarded against by the judicious use of the water, and, if necessary, may have to be met by the use of a mineral water of partially antagonistic powers.

In such cases we may pursue two parallel modes of treatment, which are either auxiliary and complementary, or are corrective of each other. For instance, anæmias, loss of tone, and cachectic conditions are so frequently the result of chronic diathetic affections, or even of such as were primarily local, that it is often necessary to add the use of restorative waters to that of those specially directed against the principal malady. Thus, nothing is more common, than for a patient going through a course of chloride of sodium or sulphur or other water, to drink a steel water of the same, or of another station.

Aix-les-Bains, Bagnoles (Orne), Chatel Guyon, Luchon, Saint-Nectaire, Uriage, each has an iron spring; and Plombières (besides having a weak one of its own) makes use of the waters of Bussang, where unfortunately there is no establishment. If we are often obliged to treat in this subsidiary way cases of anæmia going through special water-treatment for more important affections, it also happens sometimes, that the chlorosis may be accompanied by some concomitant affection, such as the remains of a bronchitis, irritability of the mucous membrane of the respiratory organs, by some strumous, eczematous, or rheumatic complication. In such a case, we must choose a station where the restorative water is placed side by side with a sulphur or a chloride of sodium one, unless the same water, for instance, that of Sylvanès, of Chateauneuf, or of Saint-Nectaire, present an union of two active principles. This is also the case with the sulphur and chloride of sodium waters of Uriage, and the similar ones with some iodine of Gréoulx, which are particularly suitable, when catarrh of the respiratory surface is associated with scrofula.

In the case of affections which require at once purgative and alterative treatment, we can also use two remedies simultaneously. Thus, skin-affections

in fat plethoric subjects] are treated at Saint-Gervais, not only with the sulphur source, but also with the one containing chloride of sodium and sulphate of soda. Montmirail offers a similar combination in its sulphide of lime water and its green purgative source. As to examples of parallel corrective cures, the debilitating effects of protracted tepid baths, or of very hot baths, or the weakening effects of strong alkaline waters, may be met by the simultaneous use of restorative waters, common iron ones, or more complex ones. At Vals the use of the iron and arsenical waters of Dominique and of Saint-Louis, has been ordered to counteract the debilitating effect of the strong alkaline waters. Other carbonate of soda waters carry their antidote with them, in containing iron at the same time. Such are the Source Mesdames at Vichy, the waters of Boulou, Neyrac, and Marcols, which ought to be ordered for feeble, gouty, or gravelly patients.

XIX. Of Successive Cures, Auxiliary or Supplementary.

Generally speaking, a patient resorts in one season only to one station, not so much because he is wearied with having gone through a complete course, as because the physician considers that the one set of waters which he has chosen should be sufficient for the cure. There are, however, many circumstances under which the improvement would be more rapid, and the success more assured, if two mineral waters were employed, one after the other, possessing qualities more or less different, but supplementary of each other, and each able of itself to contribute to the therapeutic result. Why not subject an eczematous or herpetic patient, loaded with fat, first to a reducing treatment by purgative waters, and then to the ordinary cure by sulphur, arsenic, or alkaline ones? Why not make an anæmic dyspeptic use, in the first place, iron alkaline waters, and next strongly restorative ones, or, in such a case, these same waters in reversed order? Or, take patients suffering from calculous, hepatic, or renal colics. In such cases, we ought first to attempt to favour the evacuation of concretions, or to diminish the amount of matter that can form concretions, by means of reducing treatment; in the second place, we ought to endeavour to prevent the formation of concretions, by making the bile more fluid, and the urine more watery. No doubt, up to a certain point it is possible to obtain the same objects, by using one mineral water, which acts, according to the dose, as a cathartic or as an alterative; but the first indication would be better fulfilled by specially purgative waters, and the last by waters essentially dialytic. It would, therefore, be more advantageous for patients suffering from a calculous affection of liver or kidneys to commence by a cure at Brides, Chatel Guyon, Santenay, or Montmirail, and to end by a visit to Contrexéville, Vittel, Vals, or Vichy. I recommend such a course, having often ordered it with most satisfactory results. I have observed equally good results after a season at Salins-de-Moûtiers, followed by a half cure at Aix in Savoy, in the case of lymphatic patients suffering from joint-affections.

In like manner, it would be advisable to submit cases of erethic tuberculosis, in the first instance to the milder action of the waters of Mont Dore or Royat, and afterwards to the sulphur lime waters of Allevard, Enghien, Saint-Honoré, etc., or later to the

action of the sulphide of soda waters of Amélie, Bonnes, Cauterêts, Luchon, Vernet. And a seaside cure might also be employed to supplement mineral waters. Thus, in a great number of cases this double course of treatment would be followed with decided success. What one has to avoid in such cases, is the fatigue to the patient from change of place and change of treatment. To guard against this as much as possible, we may try to select stations possessing two classes of waters, or at least two districts possessing wells that may be auxiliary and supplemental to each other. In the first category are Saint-Gervais, and Montmirail; in the latter, Andabre joined to Sylvanès, Vichy to Chatel Guyon, or even Royat to Saint-Honoré.

[Our author here sketches an outline of the German *Curs* and *Nachcurs*. The practical difficulty is to find English patients, unless those who think themselves seriously ill, who will spare time for two courses, or who are inclined to enter on them. The most popular *Nachcur*, a visit to Switzerland or to some Alpine station, is not mentioned by M. Gubler—but the French travel much less than English, Americans, or Germans.—Tr.]

XX. The Duration of Mineral-Water Cures.

The length of almost every water-cure is fixed at twenty-one days, having reference to the menstrual period, according to the old doctrine. But it is obvious, that no such arbitrary limit can be adhered to. The length of the cure must vary according to the action of the waters, and the object which we wish to attain. It may be reduced to ten days in the case of some purgative waters, and to fifteen for some simply laxative ones. At some places, as at Chatel Guyon, it is usual to divide the cure into two unequal periods, the first of ten days, and the second of only five, with an interval of quiet.

A minimum of ten to fifteen days would also be sufficient, if we choose to be contented with the stimulating action of the very hot waters, which are employed with the view of rousing torpor of the system, or of vivifying a dry and squamous eruption, to bring out an old leaven of syphilis, or to exercise any disturbing action. Such is the real or supposed test for syphilis at Luchon and other places. The cure at Mont Dore, or at Aix-les-Bains, seldom extends beyond sixteen days.

But if we wish to give to a disturbed economy a new and persistent direction, whether by establishing a new habit, or by modifying the action of the organs by the mineral principles which permeate their parenchyma, or by altering the composition and molecular structure of histological elements, it is indispensable to continue for a lengthened period the internal use of waters. The effects of mere contact with new waters may be sudden, but they are not permanent. The phenomena of impregnation of the system with therapeutic agents are slower in appearing, and also in being effaced. Twenty days are certainly never too long a time for producing such effects. Nevertheless, some have thought that the period of cure might be shortened by using forced doses. In Spain the course is often reduced to nine days, and this was formerly the practice at Bonnes. But, although enjoying the shadow of the great authority of Bordeu, this practice is radically irrational, for the factor of time cannot be replaced in molecular action by mass. Besides, too large doses produce the troublesome effects of the *poussée*, or of thermal fever, which, far from indicating saturation of the system, or that our therapeutic objects have

been attained, only show that the system has rebelled against the alterative agent.

Thus the nine-day cures should be repudiated by intelligent physicians, who will continue to order a three-weeks' course of sulphur, chloride of sodium, and most other waters. This space of time is, in many cases, insufficient to cause the deep-seated changes in the organs, on which the cure of the morbid symptoms depends. Certain alterative cures, as in constitutional maladies, such as scrofula, tuberculosis, darte, must be continued often for more than thirty or thirty-five days, allowing for a few days' rest, and for recruiting between the first season of twenty days, and the second of ten or fifteen, which ought to complete the cure.

I always advise a long stay at La Malou, at Bourbonne, Salies, Salins, Saint-Nectaire, La Bourboule, and at stations where they treat local affections of a torpid character, which are dependent on constitutional causes.

XXI. *On the Season most favourable for Mineral-Water Cures.*

There are troublesome prejudices on this subject, which it would be well to destroy. July and August appear to be the two lucky months during which drinkers and bathers press in serried columns to all stations, French and foreign, as if mineral waters cured only under the dog-star. It is all very well for prospectuses to say, 'Open from May to September;' no one hearkens to the appeal. Is this simply a matter of fashion? Not entirely so. Many stations are in the mountains, and do not in the earlier months offer a climate favourable to invalids, for instance Barèges, Cauterêts, Gastein, Mont Dore, Saint-Moritz, etc. Nevertheless, at Cauterêts, at Mont Dore, and especially at Eaux Bonnes, the second half of June and the first half of September, often offer conditions of climate most favourable to patients, more favourable indeed than in the extreme heat of summer, which is apt to bring on intestinal complications, and by its enervating influence add to the exhaustion of a thermal cure.

A great number of French stations also, situated at slight elevations, or in the more southern latitudes, admit a greater extension of the bath season. In a middle zone we find Pougues, Nérès, Evaux, the two Bourbons, Vichy, Aix-les-Bains, Marlioz, etc., where treatment would not only be possible, but more advantageous in May, June, and September, than during the official seasons.

Going south, we find on the side of the Alps, Montmirail, Aix-en-Provence, Digne, and Gréoulx; on the side of the Pyrenees, Bagnères, Adour, Dax, Salies, Saint-Christau, Cambo, and many other mineral waters, which ought to be frequented in May, June, September, and October, and to be entirely abandoned in July and August.

We possess among our stations some really winter ones—Le Vernet and Amélie-les-Bains, in the Eastern Pyrenees; and nothing would be easier than to establish some new ones in some privileged nooks of Provence, as Saint-Martin de Lantosqua, Alpes Maritimes, and in the neighbourhood of Draguignan, where there are sulphur and saline springs.

In reality, patients might profit for a much longer time than people usually suppose, by the resources offered by mineral waters. Even when I write, at the end of August, many stations are accessible, and even favourable for prolonged treatment.

Patients suffering from liver or from gravel may stay at Vichy during the whole of September, and at Vals till October.

Strumous patients may profit by Salies de Bearn and Arcachon till late in the season; so also nervous cases by Bagnères de Bigorre, or by Aix-en-Provence. If necessary, the thermal waters and the mud of Dax might be used in rheumatism all through the winter; and still more might paralytic cases be treated at the same season at Balaruc.

September and October are the two months to select, for the treatment of chronic nervous affections, at La Malou; and the same may be said of Digne and Gréoulx, for that of chronic diseases of the joints, of the respiratory organs, and of scrofulous affections. Lastly, Amélie and Le Vernet offer efficacious treatment all through the winter to those who suffer from asthma, catarrh, or tubercles.

In finishing these articles, I am happy to think, that I have pointed out to practitioners a supplement to therapeutic treatment, to bath practitioners in particular an extension of their field of action, and that I have been able to offer more consoling prospects to patients.

[I think these last observations about season very valuable. There are no patients so entirely tied down to particular seasons, by considerations of fashion, of usage, or of business engagements, as the English. A number of the *Saison d'Hiver aux Thermes de Dax*, now before me, shows that everything is being done to make a winter-station of Dax, with its abundant thermal waters. It lies between Arcachon and Pau, and has a large new establishment, a hotel containing rooms for inhalation and laryngeal douches, and also mud-baths for rheumatic, neuralgic, and paralytic patients. There are many difficulties in the way of forming mineral-water winter-stations in Provence, as suggested by M. Gubler in the conclusion of his lucid summary. Summer-stations in the hills behind Nice are much more wanted for invalids requiring a cooler climate, and who cannot conveniently go to a distance. One of them is the Saint-Martin mentioned above, of which Smollett gave some account under the name of Rocabiliare; but there is a want of houses, of accommodation, and of society now, as in his day.—Tr.]

J. MACPHERSON, M.D.

ANATOMY AND PHYSIOLOGY.

SALOMON ON THE FORMATION OF GLYCOGEN IN THE LIVER.—Virchow's *Archiv* (Band li. Heft 3) contains a long article by Dr. George Salomon of Berlin on this subject. Our space will only allow us to give a brief abstract, and we must refer to the original for almost all details. The author begins by stating that the past year has been a fruitful one as regards our knowledge of glycogeny. Brücke's improved method of estimating glycogen (*Sitzungsberichte der Wiener Akad.* Band lxi.) was a great step gained as regards accuracy. The subject naturally divides itself into a physiological and a pathological division; and Dr. Salomon occupies himself chiefly with the former, as the only sure basis for our study of the latter. He determined to investigate the glycogenic action of certain articles of food, etc.; and, for the purposes of his experiments, he defines a glycogen-former, or glycogenetic substance to be 'a substance which, being brought into the stomach, has the pro-

perty of increasing the glycogen of the liver.' To eliminate errors from incidental but ill-understood conditions as far as possible, he made many experiments, and chose but few alimentary substances. Luchsinger's interesting experiments (*Pflüger's Archiv*, Bd. viii.) are vitiated by the small number of experiments on each substance. The rabbits chosen by Salomon were killed by cutting the throat; the liver was at once removed, and rapidly cut into a vessel of boiling water by scissors. After brief boiling, the water was poured off, and gently heated over a fire in a fresh pan. The liver-substance from the first pan was then rubbed down in a hot mortar with a little sand, and the 'broth' thus formed added to the water of the first boiling. The whole was then cooked for ten to fifteen minutes, the hot decoction (0.75 to 1 litre = 26 to 35 ounces) poured on a filter of coarse linen; and the residue of liver was boiled with successive portions of 100 to 200 cubic centimètres (3 to 6 ounces nearly) of water, as long as the fluid showed opalescence. Lastly, the whole was collected on the filter and washed. The collected filtrate was concentrated to 150 or 200 cubic centimètres (4½ to 6 oz. nearly), treated after Brücke's method with iodide of mercury and hydrochloric acid; and the fluid was filtered from the precipitate mixed with two or three volumes of alcohol at 92 per cent. The glycogen thus obtained was placed on a filter, extracted with ether, dried at 115° to 120° (Cent. ?) and weighed. Salomon does not claim absolute accuracy for these experiments. Luchsinger (*Centralblatt für die Med. Wissenschaften*, 1872, no. 9) has shown how very difficult it is to completely free the liver from sugar and glycogen by large bulks of water. Salomon confirms this. In one experiment in which the glycogen yield was 0.43 gramme (= 6.6 grains), there were traces of grape-sugar found after six boilings and successive extracts with alcohol. A similar difficulty was found with glycogen. He suggests, that boiling the liver with potash might obviate this, since Bernard's experiments have recently been confirmed by Weiss (*Sitzungsberichte der Wiener Akademie*, July, 1870, Band lxiv.), and show that glycogen resists the action of potash. Other precautions are mentioned in the paper. He states that the bulk of the precipitate by Brücke's process consists of a substance soluble in hot soda-lye, which is again precipitated by cautious addition of acetic acid. He once obtained a precipitate by hydrochloric acid alone, which was coarsely flocculent, and soon settled, but acquired no increased bulk by adding the mercury solution.

Experiments were also made as to the amount of sugar in the alcoholic extracts. The animals were allowed water only, and no food, for from two to three and a half days.

[The mean of Dock's, Weiss's, and Salomon's experiments on seven animals fasting from one and a half days was six-tenths of a grain only, traces only being found twice, and no trace once. Dr. Salomon's conclusions are as follows.

1. The liver contains sugar during life.
2. Gelatine is a glycogen-former.
3. So is olive-oil, in less degree.
4. Milk-sugar and grape-sugar are also glycogen-formers. Mannite is apparently not so.
5. The primary acetyl-derivative [Monacetyl saccharose = $C_{12}H_{21}(C_2H_3O)O_{11}$] of cane-sugar is decomposed in animal bodies into acetic acid and sugar: the former is probably burnt up, the latter acts in the ordinary way as a glycogen-former.

Some of his own experiments with gum, grape-sugar and glycerine were vitiated by accidental causes. Similar objections (idiosyncrasies, disease in subjects of experiments, etc.) lie against the experiments of others. He considers the results of Bernard, and indeed of nearly all who experimented before last year (and did not use Brücke's process), as vitiated by the enormously high figures, due to admixtures of various kinds. The whole paper is of extreme interest to physiologists and practical physicians.—*Rep.*] W. BATHURST WOODMAN, M.D.

EWALD ON GASES IN HUMAN TRANSUDATIONS. A. C. Ewald (Reichert and Du Bois-Reymond's *Archiv*, 1873: Abstract in *Centralblatt für die Medizin. Wissenschaften*, no. 37, 1874) obtained the fluid to be investigated by means of a trocar, pointed with an elastic tube, and caught it directly over mercury, in the apparatus of Pflüger provided with three stopcocks. By this arrangement the admixture of air was completely excluded. As the pumping out of the gases could be always immediately undertaken, the tube was cooled in several experiments with ice-water, in order to avoid decomposition. The results of this method, compared with those obtained in the usual way, showed that this procedure was superfluous. For the analyses, pleuritic effusions and transudations in different stages were exclusively employed. Ascitic fluids were avoided, because in them there was a possibility of diffusion from the intestinal canal. The author divides the exudations employed into purely serous exudations, chronic exudations, gradually becoming purulent, and acute purulent exudations. To these, on the one side, belong the oedemata, on the other, the pure pus of abscesses. The quantity of gases in oedematous fluid does not vary greatly from physiological lymph. The loosely combined, carbonic acid in Case 1 was 16.91 vol. per cent., in 2, 16.63; the firmly combined in Case 1, 6.95, in 2, 23.7. The serous pleuritic exudations showed an increase of the whole quantity of carbonic acid, with the duration of the condition; it increased from 33.84 vol. per cent. to 63.84 per cent. Only in one case was there an exception; but in this case pneumo-thorax coexisted, and carbonic acid could be removed by diffusion. The more purulent exudations showed that the value for the carbonic acid, however, depends upon another factor; the sum of carbonic acid contained in an exudation is, *ceteris paribus*, smaller, the more its condition approximates to pure pus. The carbonic acid is almost exclusively contained in pus-serum; the more the latter exceeds in proportion to the pus-corpuscles, the less must be the value for the carbonic acid. Concerning the increase of carbonic acid with the duration in the more serous exudations, it is shown that it is chiefly the firmly combined carbonic acid which is first expelled by the addition of acids; here there is quite a regular increase. For the explanation of these facts, there come into consideration, 1, the passage of loosely combined carbonic acid into firmly combined carbonic acid in consequence of the increase of the partial pressure; 2. the addition of carbonates by endosmose; 3. the absorption of watery constituents. In the purulent exudations the quantity of fixed carbonic acid sinks continually, until in the pus of an abscess it equals the oxygen. There are two ways of explaining these phenomena; increase of the alkalinity and the capability of pus-corpuscles

to expel carbonic acid as the red blood-corpuscles do. An increase of alkalinity could not be proved, so that there only remains the second possibility; and by special experiments it was, in fact, shown that the pus-corpuscles—pus free of gases—are capable, on pumping out, of expelling carbonic acid from pure simple carbonate of soda, quite in the same way as mineral acids. Small quantities of oxygen and nitrogen could be detected in all cases, and the quantity of oxygen and nitrogen was under 1·8 per cent. As the quantity of these two sorts of gas is nearly the same as in blood-serum, and does not increase with the addition of pus-corpuscles in proportion to the serum, it follows that the pus-corpuscles and white blood-corpuscles contain no oxygen, or only traces, *i.e.* are not oxygen-carriers like the red ones. Hydrogen, sulphuretted hydrogen, and carburetted hydrogen were found once only in a putrid exudation. The reaction of oedematous fluid, as well as of the serous exudations, was always alkaline; that of pronouncedly purulent exudations, as well as of pure pus, more or less acid. The specific gravity varied from 1005 to 1026.

SCHMIDT ON THE DISSOCIATION OF OXY-HÆMOGLOBIN.—Albert Schmidt (*Centralblatt für die Medicin. Wissenschaften*, no. 46), under Preyer's direction, examined the heart-blood of guinea-pigs and frogs micro-spectroscopically with exclusion of air, and then tested the oxygen-extracting action of different tissues. The following facts were noted.

I. The cardiac blood of *living* foetal guinea-pigs constantly contains oxy-hæmoglobin before the first respiration.

II. The cardiac blood of grown-up animals contains:—

(a) Much oxy-hæmoglobin after death by, 1, hunger (in warm-blooded animals); 2, freezing (in warm-blooded animals); 3, blowing of air into the jugular veins; 4, poisoning with hydrocyanic acid (in the frog.)

(b) Hæmoglobin free of oxygen, and only traces of or no oxy-hæmoglobin after death by, 1, closure of the trachea and drowning; 2, pneumothorax; 3, puncture in the respiratory centre; 4, blows on the head; 5, respiration of rarefied air; 6, respiration of hot air; 7, freezing in the frog; 8, poisoning with nitrobenzol, chloroform, alcohol, arsenuretted hydrogen, iodine, physostigmin, strychnine, quinine, nicotin, potash-salt-petre (frog), soda-salt-petre (frog.).

(c) At one time oxy-hæmoglobin is in excess, at another hæmoglobin free of oxygen; or both may be in nearly equal quantities after death by, 1, poisoning with arsenious acid (in warm-blooded animals); 2, poisoning with prussic acid (*ditto*); 3, injection of steinölin (petroleum) into the jugular vein.

III. Many experiments on dissociation made with tissues gave the following results.

Muscles of the frog which were tetanised continually, dissociated oxy-hæmoglobin, after removal from the body (*ceteris paribus*), more quickly than those which were not active, but not so quickly as dead muscles, and the dissociation set in before the change of the spectrum by lactic acid.

Brain and liver withdrew oxygen from the oxy-hæmoglobin very rapidly in watery solutions, the latter itself at a temperature of 0° Cent.

Fungi placed in solutions of blood produced a rapid dissociation and then changes of the spectrum, such as are produced by dilute acids.

Quinine prevents the dissociation of oxy-hæmoglobin by fungi, but not that through brain and liver substance.

LANDOIS ON THE INFLUENCE OF THE GASEOUS CONTENTS ON THE SOLUBILITY OF THE BLOOD-CORPUSCLES.—Professor Landois of Greifswald, (*Centralblatt für die Medicin. Wissenschaften*, no. 27, 1874), says that if different portions of the same blood, be treated with carbonic acid, oxygen, and nitrous oxide, the red blood-corpuscles exhibit great varieties with regard to their solubility. The corpuscles charged with carbonic acid are dissolved much sooner than the others. Certain reagents which are unable to dissolve blood charged with other gases, produce the lake colour at once in blood charged with carbonic acid. The reagents employed were salts of the bile-acids, very dilute solution of chloride of sodium, and serum of dog's blood for the blood of rabbits and guinea-pigs. Blood charged with nitrous oxide stands between that charged with carbonic acid and that charged with carbonic oxide. The blood-corpuscles of all sorts of blood become round before their solution, and show exceedingly fine points. Perhaps the condition of the hæmoglobin in the cells at the time may account for this.

WILLIAM STIRLING, D.Sc. M.B. (Edinburgh).

LANDOIS ON THE FORMATION OF FIBRIN FROM THE RED BLOOD-CORPUSCLES.—In a second part of the same paper, M. Landois describes the formation of fibrin as being dependent on the dissolved corpuscles. If a drop of defibrinated rabbit-blood be brought into a drop of frog's serum, the cells aggregate together, and become sticky on their surfaces. The cells soon become globular, and those cells lying towards the periphery allow the blood-colouring matter to pass out. This discolouring gradually extends towards the centre of the drop, and at last only a heap of stroma remains. The stroma-substance is very tough and viscid. At first the contours of the cells can be detected; and, when the stroma has been agitated to and fro, the cellular contours disappear, and viscous fibres and stripes are observed. Step by step the formation of fibrous masses from the dissolved mammalian cells can be observed. The author thinks this fibrin should be called 'stroma-fibrin' in opposition to the ordinary fibrin or plasma-fibrin, which is formed without solution of the blood-corpuscles. The two kinds of fibrin may possibly be chemically distinguished from each other. In transfusion, if dissolution of the cells occur, then, of course, the formation of stroma-fibrin may take place. The coagulation occurs the sooner, the more serous the blood. Animals in a state of asphyxia, into whom heterogeneous blood was introduced, showed the most extensive coagulation.

PAULOWSKY ON THE COURSE OF THE FIBRES IN THE POSTERIOR COMMISSURE OF THE BRAIN.—In Siebold and Kölliker's *Zeitschrift für Wissenschaftliche Zoologie*, vol. xxiv. Heft 3 (September 16, 1874), Dr. Paulowsky records the result of his investigations into the structure of the so-called posterior commissure of the brain. This body has been variously described; most authors, however, believing that its fibres run transversely between the two thalami optici, thus serving to connect the two hemispheres of the brain. According to Arnold, the commissure really consists of two factors, one of which belongs to the 'Schleifenregion' the other

to the hemispheres. [The 'Schleife' answers to the *lemniscus* of Reil. The first factor probably answers to the commissure of Wernekinck.—*Rep.*] Luys has remarked a crossing of the nerve-fibres in the commissure. Meynert describes this structure as the crossing place of the anterior and posterior crura of the corpora quadrigemina, which, after crossing, pass over into the tegmentum ('Haube') of the crus cerebri. Besides this it is in communication with the pineal gland and the 'ganglion habenulæ.'

Dr. Paulowsky made his observations on preparations from man, sheep, dogs, and rabbits. He arrives at the following conclusions.

1. The so-called posterior commissure consists of coarse fibres running down from the brain to the tegmentum of the crus cerebri.

2. These fibres have a four-fold origin—

(a) In the pineal gland ;

(β) In the frontal lobe of the brain (through the anterior peduncle of the thalamus) ;

(γ) In the temporal lobe and in the fissure of Sylvius (through the inferior peduncle) ; and

(δ) Probably in the thalamus itself.

3. In the tegmentum one portion of the bundle of fibres runs with the 'Schleife,' while another lies to the inner side of the same.

4. Commissural, or bridge-like fibres, do not exist at all in the posterior commissure.

5. Therefore the term 'commissura posterior' is an incorrect one, and it would be more advisable to call this region of the brain the crossed tract of the tegmentum—'tractus cruciatus tegmenti.'

J. C. GALTON.

BAJARDI ON ANOMALIES OF ORIGIN OF THE SUPERIOR THYROID AND LINGUAL ARTERIES.—In a paper in the *Gazzetta delle Cliniche* for October 13, Dr. D. Bajardi states that, while preparing an adult subject for lessons in operative surgery, he found that the right superior thyroid artery, in place of arising as usual from the external carotid, had its origin from the common carotid a little more than an inch from its division. It then passed slightly upwards behind the sterno-hyoid and omo-hyoid muscles, and was distributed to the thyroid body. The left superior thyroid also arose from the common carotid, but at the level of the enlargement which the vessel presents before its division. The vessel on the right side was much more slender than the other, and did not give off the superior laryngeal, which arose from the external carotid. The bifurcation of the common carotid was a little below the level of the upper margin of the thyroid cartilage.

Dr. Bajardi observes that the presence of the superior thyroid artery in the situation described might be a source of embarrassment to the surgeon in proceeding to tie the common carotid artery, as, seeing the thyroid artery in the wound, he might suppose that he had not cut down on the common carotid. He would also be embarrassed if his object were to tie the superior thyroid itself, not finding it in its normal situation.

In 117 cases, Dr. Bajardi has found the superior thyroid arising from the common carotid in 37 or 31.62 per cent. This proportion appears greater than is generally admitted ; Quain, for instance, gives 41 cases in 292, or 14.38 per cent. In the thirty-seven cases, the thyroid artery arose in thirty-three at the level of the carotid sinus, and in four only lower down. In one case, Dr. Bajardi found a

double superior thyroid artery ; both branches arose from the common carotid, one 0.7 inch, the other 0.3 inch below the bifurcation. In four cases, he has found the superior thyroid having a common origin with the lingual ; in two cases from the common, and in two from the external carotid artery.

In an adult female subject, the right lingual artery came off from the common carotid about two-fifths of an inch below the bifurcation, while the superior thyroid had its origin from the external carotid muscle higher than usual. The lingual artery ascended along the lower side of the carotid as high as the greater course of the hyoid bone, and then, passing behind the hyo-glossus muscle, entered the tongue. The dorsal artery was not supplied from the lingual, but from the facial artery.

Dr. Bajardi has in one case seen the lingual artery have a common origin with the superior maxillary.

MEDICINE.

LOCKHART CLARKE AND GOWERS ON A CASE OF PSEUDO-HYPERTROPHIC MUSCULAR PARALYSIS.—This case (by Dr. Lockhart Clarke and Dr. Gowers, in vol. lvii. of the *Medico-Chirurgical Transactions*) presents for our consideration several points of great interest, both clinically and pathologically. In the first place, here is no history of an hereditary disposition to be obtained. Both the parents of the child are living and in good health, and no other of their children has manifested any disposition towards the malady. An hereditary or family tendency has been pronounced by some observers to be a feature of this affection of the muscles, as also in muscular atrophy. In the next place, the sex and period of life are noteworthy. The disease is essentially one of male childhood, although the reporter has at the present time a case under observation in which the symptoms first manifested themselves after puberty.

Another point observable in the case before us is the obscurity in which the affection has hitherto been involved, so that it has, until recently, escaped recognition.

Referring to the history before us, we read that 'in infancy the boy was well nourished and apparently healthy, but began to walk later than other children, not until he was two and a half or three years old, and then in a peculiar way. About that time, his calves were observed by his mother to be unusually large. As he grew older the peculiarity in his walk became more marked ; he carried his body bent slightly forward, and walked with a swinging movement. He was never able to walk far, but when five years old could walk, in the manner described, about a mile. At this age the calves were noticed to be very large, the thighs were thought to be about the normal size ; the arms were fleshy, but were not noticed to be particularly large. About the age of eight years the heels were observed to be somewhat drawn up. As this increased he became unable to walk, and after giving up walking he had some difficulty in straightening the knee-joints, and the elevation of the heels increased.' Without quoting all the details of the history of this case, we remark that so little was its pathology understood, that in 1867 Sir William Fergusson advised, and in 1869 Mr. Wm. Adams performed

division of both Achilles tendons. By the help of steel supports carried up to the hips he was for a time enabled to walk with assistance; the benefit, however, was, after all, but slight, and in the same year, the supports being discontinued, the boy never stood or walked again. From this time there was a steady loss of power with wasting of muscles both in the upper and lower extremities. In March, 1873, having reached the age of fourteen years, the boy died with pulmonary disease. With the utmost respect for the opinions of two so highly distinguished surgeons, there existed from the first, pathological reasons against the success of any surgical operation.

Dr. Friederich, of Berlin, in his exhaustive treatise on muscular atrophy, expresses the opinion that it is essentially the same disease as muscular atrophy, with certain modifications arising out of an excess of fatty and connective tissues. The case before us bears out this conclusion, since wasting of the muscles, not only of the upper extremities, as commonly met with in this form of the disease, but of the lower extremities also, including even the calves, was prominently noted before the intercurrent lung-disease terminated the life of the sufferer. The authors, however, add that in no case hitherto recorded has atrophy of the muscles of the calves, previously increased in size, been noted.

The *post mortem* examination, as related by Drs. Lockhart Clarke and Gowers, seems to confirm this last-named inference. 'Each gastrocnemius muscle presented the appearance of a mass of adipose tissue. On section, it was pale yellow and greasy to the touch. No trace of red tint could be seen in it. Under the microscope it consisted for the most part of distended fat-cells, which lay between, and separated widely, bundles of muscular fibre. The fat-cells were quite similar to those of an ordinary lipoma; they varied in size from $\frac{1}{250}$ to $\frac{1}{1000}$ of an inch. The muscular fibres ran, several together, through the adipose tissue. Some were of normal size, others much less; their diameter varied from $\frac{1}{1000}$ to $\frac{1}{3500}$ of an inch.' The muscular fibres were in some parts but slightly changed; in some the striation had disappeared, and was replaced by granules distributed uniformly throughout the fibre; in other instances the fibres had become mere sheaths.

The inch and a half of new tendo Achillis of each leg was readily distinguishable by the grey colour and translucency of its tissue as compared with the opaque pearly lustre of the old tendon, while the line of junction both above and below was traceable in the dovetailing of the new with the old fibres.

With reference to the nervous centres, it is noted that the microscope revealed varied and extensive lesions of the spinal cord. 'These lesions began from above downwards, at the level of the second cervical nerves. There was disintegration in a greater or less degree of the lateral grey network which is so conspicuous in this region between the corpus cornu posterioris and the tractus intermediolateralis, and through which the spinal accessory nerve makes its way into that tract. The tract itself was to a certain extent in a state of incipient disintegration, and on one side was, in many sections, traversed by a dilated and congested blood-vessel around which the tissue had begun to suffer. The white columns were

not perceptibly altered, but one lateral half of the anterior white commissure was entirely destroyed, and replaced by granular *débris*, by exudations and extravasated blood-corpuscles, which also filled the triangular space at the bottom of the anterior fissure. On descending through the rest of the cervical region the same kind of morbid changes, to a greater or less extent, were found at different levels, while the anterior and central grey substances on each side was the seat of extensive disintegrations. A similar lesion existed in some of the posterior nerve-roots.' Areas of disintegration were traced as low down as the conus medullaris—in fact, in no region of the cord does it appear that a section could be made that was free from very grave pathological appearances. Among these, it is mentioned that 'both the lateral and posterior white columns were in many sections much damaged by sclerosis, consisting of a variable degree of disintegration of the myelin or white substance of the longitudinal fibres.'—[Do the authors by this last description intend to express the presence of *miliary* sclerosis? If so, their description is at variance with that of this form of degeneration as given by Drs. Batty Tuke and Rutherford, and the present writer.*—*Rep.*]

W. B. KESTEVEN.

SCULL ON PHTHISIS WITH UNCONSCIOUSNESS FOR FIFTEEN MONTHS.—Dr. B. F. Scull reports in the *American Medical Weekly* (quoted in the *New York Medical Times*, August 15), a case in which a man who had been suffering from severe bronchitis, with symptoms of incipient phthisis, for several months, fell into a condition resembling catalepsy. Although eating and drinking whatever was offered, he seemed entirely indifferent as to the character of the food, and wholly unconscious of his surroundings, of his condition, of what he was doing, or of what was being done for him. His fæces were passed into a diaper, and it was necessary to keep him cleansed without any co-operation on his part. After remaining in this condition for fifteen months, he suddenly recovered consciousness, but fell into a rapid decline, and died a year later.

NELSON ON DIPHTHERIA TREATED BY LOCAL APPLICATION OF SUBSULPHATE OF IRON.—Dr. A. W. Nelson, of New London, Connecticut, extols (*New York Medical Journal*, January, 1874) the efficacy of the local application of persulphate of iron in diphtheria. In mild cases he uses liquor ferri subsulphatis, and pure water or glycerin, in equal parts, or two of the latter to one of the former; in severe cases he uses the liquor ferri subsulphatis in its full strength. Vomiting may be induced by it at first, but this is rather beneficial. For subsidiary gargles, water, chlorate of potass solution, and lime are, he considers, all useful. The iron as a gargle is disagreeable, from blackening the teeth, and staining white clothes. These effects are best obviated by employing a large camel's-hair pencil well washed after using. Of forty cases treated by this method there were, he says, only three deaths. Of the three deaths, one was moribund when first seen; the second was not treated locally with the subsulphate.

* See *Edinburgh Medical Journal*, 1868 and 1869; also *British and Foreign Medico-Chirurgical Review*, 1869, 1873, and 1874; *St. Bartholomew's Hospital Reports*, vol. viii.; and *Journal of Mental Science*, 1871.

SURGERY.

DENEFFE AND VAN WETTER ON ANÆSTHESIA BY INTRAVENOUS INJECTION OF CHLORAL: ABLATION OF CANCER OF RECTUM.—Professor Deneffe and Dr. Van Wetter (*Bulletin de l'Académie Royale de Médecine de Belgique*) describe the case of M. De W., who had suffered several months from a recurrence of cancer in the rectum, for which he had been operated upon three years previously.

On June 4, at 5.34 P.M., a gold trocar and cannula was passed into the radial vein, and the injection of a solution of ten grammes of chloral in thirty of water was commenced. The syringe was provided with a very fine sieve, to prevent any solid particles from entering the blood. The solution was injected in small quantities every two or three minutes; but the anæsthesia was not complete till 6.15, *i.e.* forty minutes after the beginning of the injection. The quantity injected now amounted to 7.50 grammes (about 116 grains) of chloral. The operation was commenced immediately, but at 6.20 fifty centigrammes more of chloral was injected. At 6.30 the operation terminated. Attempts were now made to awake the patient by applying, over the course of the pneumogastriacs, the rheophores of a strong electric machine. This failed to arouse him. Towards 8 P.M. sensibility commenced to return. At 8.30 he moved slightly when pinched. At nine he answered questions, but he was not fairly awake till 5 A.M. He made a good recovery.

[As the patient was forty minutes in being anæsthetised, and more chloral had to be injected during the operation, and as the symptoms were such as to cause electricity to be used, it is probable that ether or chloroform by inhalation would have answered at least as well. The case, however, is one of great interest, as showing how effective chloral is as an anæsthetic when thus used. Those who have sufficient confidence in the safety of intravenous injection, will doubtless be induced to repeat the experiment in cases where the operation was likely to produce severe pain for several hours.—*Rep.*]

J. T. CLOVER.

MARCACCI ON A CASE OF RECURRENT CANCER OF THE PENIS.—In a case described by Professor Marcacci in *Il Movimento Medico-Chirurg.*, for September 20, a man named Ubaldo Brocarini had had his penis amputated for epithelial cancer. Twenty-five days afterwards, the disease had attacked the whole of the corpora cavernosa as far as their attachments to the rami of the pubic bone. There were two enlarged glands in each inguinal region. As the patient insisted on an operation being performed, Dr. Marcacci made a circular incision just above the line of the former amputation through the skin and connective tissue, down to the fibrous investment of the penis. From this incision another was made perpendicularly as far as the symphysis pubis; and a third was carried along the inferior surface of the penis (which was only about four-fifths of an inch long) though the raphe of the scrotum, and nearly an inch along the perineum, so as to expose the bulb of the urethra. The scrotum was thus divided along the middle line without exposing the testicles. Dr. Marcacci carefully dissected the skin from the stump of the penis and from the two parts into which the scrotum had been divided, so as to expose the urethra and the crura of the corpora

cavernosa. Believing that the urethra would become retracted into the perineal fascia if cut at the same level as the corpora cavernosa, Dr. Marcacci divided the canal transversely at a point where it was healthy near the bulb, and, having introduced a large gum-elastic catheter, dissected it out as far as the bifurcation of the corpora cavernosa. The catheter and urethra being held aside by an assistant, the operator drew down the penis so as to render the suspensory ligament tense, and cut it through with a stroke of the knife, which was then carried between the penis and the os pubis to the subpubic ligament. On proceeding to dissect the crura from their attachments to the ischio-pubic rami, they were found to be healthy, and were cut through without further dissection. The two dorsal arteries and an artery of the corpora cavernosa required ligature.

The symphysis pubis was covered in by the two flaps of skin from the stump of the penis, and the two sacs into which the scrotum was divided were united separately by five points of interrupted suture. At the bottom of the triangle left between the sacs was the urethra; this was incised anteriorly and posteriorly, and the two lateral flaps were united to the wound by suture.

Four days after the operation the patient had a severe rigor, followed by great increase of temperature. In spite of the administration of quinine, the febrile attacks returned, diarrhoea set in, the skin assumed an intense yellow colour, the wound sloughed, the urine became turbid and fetid, the cerebral functions were disturbed, the gangrene extended to the scrotum, and a small portion of the urethra fell off; vomiting and coma set in, and the patient died nine days after the operation.

At the necropsy, thirty-six hours after death, six small purulent deposits were found at the base of the right lung, and one at the base of the left. The heart was flabby, the spleen was softened, and the liver was in an advanced stage of putrefaction. The scrotum was emphysematous and black, and the walls of the urethra in the neighbourhood of the wound were of a dark colour.

Dr. Marcacci remarks that a similar operation had already been performed by Rizzoli and by Baroni.

TONOLI AND SCARENZIO ON THE TREATMENT OF VARIX BY INJECTION OF HYDRATE OF CHLORAL.—In an article in the *Gazzetta Medica Italiana Provincie Venete*, nos. 19 and 20, 1874, Dr. Tonoli, after quoting Professor Porta's memoir on the radical cure of varix [see LONDON MEDICAL RECORD, March 4, 1874] reports a case under his own observation.

A man, aged forty-nine, had for a long time been the subject of varix of the internal saphena vein, extending from two finger-breadths above the ankle to the groin, where the vein was distended into an ampulla of a dark-blue appearance. At the middle of the leg, two finger-breadths above the knee, and near the middle third of the thigh, there were groups of large tortuous branches, without any trace of clots. Dr. Tonoli made a solution of equal parts of hydrate of chloral and water, and, having made the patient stand erect for five minutes, injected into the veins at each of four separate points, eighty centigrammes (about twelve minims) of this solution: the total quantity used being 3.20 grammes (about fifty minims). After the first injection, there was some escape of blood when the needle was removed. The vessels became obliterated at all the points where

injection had been made. On the fifth day, there was distinct induration in the course of the saphena. It extended to the collateral groups, which on the ninth day were found to be harder. Slight phlebitis occurred at the injected points. The external saphena vein gradually became reduced in size, so as to be scarcely visible; to the finger it felt as a long cord. In two months and a week the cure was complete.

In a case reported in *Commentarii di Medicina e Chirurgia*, fasc. 1, 1874 (*Gazzetta delle Cliniche*, September 22) Dr. Scarenzio had nearly succeeded healing an ulcer by skin-grafting. As perfect healing, however, was retarded apparently by the presence of varicose veins, he injected into these half a grain of chloral dissolved in water. A coagulum was formed; and in a few days the ulcer was completely healed.

GASPARINI ON TREATMENT OF CALLOUS STRICTURE OF THE URETHRA BY GALVANIC CAUTERY.—In the *Liguria Medica* for December 10, 1873 (quoted in *Gazzetta delle Cliniche*, October 13), Dr. Gasparini describes the case of a young man, the subject of old callous stricture of the urethra, who had had total retention of urine for twenty-four hours. The galvanic cautery (Pischel's apparatus) was applied by Dr. Gasparini and Dr. Michelini, and immediately on its removal the patient was able to pass urine. At the end of three days the urine escaped without trouble, and the urethra remained pervious at the end of three weeks.

OBSTETRICS AND GYNÆCOLOGY.

STADFELDT ON TRISMUS NEONATORUM.—Professor Stadfeldt of Copenhagen, gives (*Archives de Tocologie*, July, 1874) the statistics of the cases of trismus of new-born infants that have occurred in the Lying-in Hospital in Copenhagen during twenty years (1853–1872).

Since his appointment to the direction of the hospital (1865), the disease has not been seen within its walls, and only exceptionally in the affiliated houses (*maisons affiliées*). Whilst he was only assistant-physician the cases were numerous, but in the early part of this century the ravages amongst new-born children in the hospital were fearful. These statistics are carefully analysed, with the hope of explaining the causes of this fatal malady in times past from a hygienic point of view. The pathology of the disease is not considered. There were 93 cases out of 20,806 infants born alive, which gives a mortality of 1 in 224. Of these, 51 were boys and 42 girls; 50 of the mothers were multiparæ, and 43 primiparæ. The proportion of multiparæ to primiparæ admitted into the hospital was as 1·4 to 1. Neither the sex of child nor the duration and difficulty of the labour seem to have any particular effect in the production of the disease. Death took place on the fourth day in 1 case, on the fifth in 3, on the sixth

in 13, on the seventh in 29, on the eighth in 25, on the ninth in 9, on the tenth in 7, and on the twelfth in 1. More than half the cases died on the seventh and eighth days. Of the 20,806 children born in connection with the hospital, there were 10,040 born in the hospital, of whom 11 had trismus, or 1 to 913; and 10,766 outside the hospital, in the *maisons affiliées*, of whom 82 had tetanus, or 1 in 131.

As soon as a woman in labour presents herself at the hospital, she is examined. If it be likely to be a natural labour, she is sent to a *maison affiliée* to be confined; on the other hand, if any difficulty be anticipated, she is admitted into the hospital.

These *maisons affiliées* are situated in various parts of the town; in them the parturient women are boarded out amongst particular families. [It will be observed that the danger of trismus arising is seven times greater amongst the externes than the internes.] This is believed by Dr. Stadfeldt to arise from certain conditions connected with the *maisons affiliées* as hitherto conducted.

It has always been maintained that trismus neonatorum showed itself during epidemics of puerperal fever. There are tables given showing the reverse to be the case; for instance, the total mortality *per mille* from trismus during the twenty years was four only, whereas from puerperal fever it amounted to thirty-five *per mille*. Again, during particular years where there were epidemics of puerperal fever, in one year for instance, the mortality was sixty-four *per mille* from fever, and one *per mille* from trismus. In the year 1854 there was an epidemic of trismus, the mortality being eleven *per mille*, from puerperal fever only seventeen *per mille*. Besides, the hygienic conditions in the *maisons affiliées* are much more favourable to lying-in women than in the hospital, as statistics have conclusively proved. Dr. Stadfeldt does not consider that trismus in any way depends upon conditions unfavourable to the puerperal state.

Most of the cases of trismus occur in the hot months, especially August and September. One-fourth of the whole number occurred in those particular months. The *maisons affiliées* afford excellent opportunities of investigating the hygienic conditions that conduce to this disorder. Of the eighty-two cases of tetanus, in the thirty-four *maisons affiliées*, in five only of the families was the appearance of trismus so frequent as to permit a supposition that there was a disposition proper to this disease. During the years 1853–63, in one of these places it showed itself eighteen times; in four others five times in each; making in all thirty-eight out of the sixty-six cases that occurred in those years. The other twenty-eight instances happened not more than once or twice in separate houses among the remaining twenty-nine. It was found that each of the families, in which there was this excessive mortality, had two beds for the reception of patients, and these were suppressed in 1864. Since then, there have been only sixteen cases in the *maisons affiliées*. The houses with two beds received during the year from 50 to 100 per cent. more cases than did the others, with one or two exceptions, where there were also two beds, but no deaths. It was eventually found necessary to cease sending cases to the house in which eighteen instances were observed, as no amount of quarantine or intervals of rest appeared to have influence in arresting the scourge. The writer concludes that houses with two beds dispose more to trismus than those with one bed, through their more frequent occupation.

That the disease is endemic in its restricted sense is partially disproved by the fact that, in the house where there were eighteen deaths, the proprietress changed her residence three times without stopping the plague. In another instance the affection followed the occupants. The other three families had lived in the same houses for eleven years.

The birth-place, of itself, exerts not the slightest influence on the etiology of trismus.

In the four above mentioned *maisons affiliées*, the midwives slept in the house and directed the lying-in state just as in any ordinary case; previously to 1861 these affiliated places were in the houses of the midwives. It was then thought that perhaps the personal superintendence or malpractice of these women had something to do in producing the disease. In one instance, a Madame H. (*Monatsschrift für Geburtskunde*, vol. xxxi. 1868, vol. xxxiii. 1869) lost no fewer than fifty infants in four years, and was in consequence compelled to give up practising as a midwife. Bathing the infants in too warm water was, in her case, considered the cause of the disease. That this was not the case in these five houses, Dr. Stadfeldt is convinced, as the babes were never bathed except when they were born asphyxiated. As a rule, malpractice is not the cause of trismus, for Mdle. W., who had the 18 cases, lost 15 out of 189 births during the first five years, whereas from 1858 to 1863 she lost only 3. It should be viewed rather as an infectious if not a contagious disorder; this would help to explain Mdle. W.'s mortality, and also assist in comprehending the following unique case.

The most skilled and the best midwife of the institution had, during the months of September and October, 1862, four cases in her practice. One occurred in her own house, the others in two separate *maisons affiliées*. Neither before nor since has she had a single instance; although she has assisted in the hospital, and latterly has practised amongst the best families under the directions of the ablest medical men. In this woman, it could be neither malpractice nor neglect of proper hygienic measures; the writer consequently believes that very probably there exists a specific contagium for trismus.

It was much to be regretted that information could not be obtained of the cases of trismus that occurred simultaneously in the private practice of the midwives.

In conclusion, the author remarks on the great advantage of having these *maisons affiliées* attached to a lying-in hospital, as by this means the admission of patients can be regulated according to circumstances, and at any moment the hospital can be closed without any difficulty, while the women having letters of admission are duly provided for.

They originated through having to provide places of confinement for women during the erection of the present hospital. It makes teaching a little more difficult, but the disadvantages bear no comparison with the great advantages. They act as safety-valves for a lying-in institution, which could only otherwise be obtained by a large increase in the number of beds, which, even if it were possible, would not be desirable in a hospital of this kind. On more than one occasion during the last few years, puerperal fever has been wiped out by the aid of these affiliated houses. In the sad years of 1860-64 it was powerless, as the fever got into the 'houses.' There is, indeed, a great danger that the midwives who attend these 'houses' may spread puerperal

fever amongst their private patients in the town; but, through prohibiting repeated vaginal examinations by the midwives, this plague has been arrested, both in the 'houses' and in the town during epidemics of fever. The *maisons affiliées* are placed under surveillance; no more than one bed is permitted in a family, and two or three weeks are allowed to intervene between the cases, the bed being in the meantime renewed. Whenever a lying-in woman is seriously attacked, she should be immediately transferred to another hospital, as from sad experience Dr. Stadfeldt is firmly convinced that the demise and corpse of a puerperal woman is most dangerous in any lying-in institution or 'house.'

In conclusion, any midwife who has attended a case of puerperal fever should be immediately prohibited from attending any more cases for a time.

TWO CASES OF REDUCTION OF CHRONIC INVERSION OF THE UTERUS.—Dr. James P. White, of Buffalo, New York, publishes two cases, being the tenth and eleventh of his series. Since 1856, the date of the first case of reduction, Dr. White has had nine similar cases, exclusive of the two now reported, which he has published from time to time in the *Buffalo Medical Journal*, April, 1856, and in the *American Journal of the Medical Sciences* for July, 1858, and April, 1872. In the latter paper he gave a sketch of his repositior. These two additional cases go far to prove the author's assertion, made when publishing his cases in 1872, 'that every case was capable of being reduced without any reserve.'

The following is Dr. White's method of operating. The woman is placed on her back and drawn to the edge of the bed, the feet resting on the laps of two assistants, he then kneels down in front of the patient, between her legs. The uterus is seized with the right hand, and compressed for some time, so as to render it more pliable; gentle pressure is now made on the fundus by means of the uterine repositior in the line of the axis of the pelvis. The left hand is kept free for manipulating the upper end of the uterus, either *per rectum* or through the abdominal walls. This repositior consists of a stem of wood or India-rubber about ten inches long, slightly curved, with one end cupped and covered with a soft rubber, so as to fit the fundus of the uterus. The other extremity has a spring attached to it, which is fixed against the operator's breast; a pressure of about eight or ten pounds is exerted. The uterus is squeezed by the hand. When the fundus is so far reduced as to be embraced by the cervix, the repositior is withdrawn and a large rectal bougie used.

Case 1. This was a woman, aged forty-six. She was attended by a midwife twenty-two years previously, who in removing the placenta, inverted the uterus. The patient being anæsthetised, a small ovoid body, about the size of a hen's egg, was found hanging by a narrow pedicle in the vagina, continuous with its upper and smaller extremity. By some of the medical men present it was doubted to be the uterus.

In this case it took one hour and fourteen minutes to reduce the fundus above the os. The assistant completed the operation in sixteen minutes. The whole operation occupied one hour and a half. The patient made a good recovery.

Case 2. The uterus had been inverted for over six years, from extraction of the placenta at the patient's second labour by an irregular practitioner.

The patient was exceedingly weak and anæmic from continued loss of blood. She was anæsthetised. A complete *cul-de-sac* could be found encircling the entire constricted portion of the tumour. The left hand was used in this instance to compress the uterus.

At the end of thirty minutes no impression was made 'on the tumour; the hæmorrhage was slight, and the constriction the same. At the end of the second thirty minutes the tumour was felt softer, and there was little bleeding.

During the next thirty minutes the pulse became quickened, and the tumour more soft and compressible. A large-sized gum-elastic rectal bougie was substituted for the repositor or 'egg-beater,' as it is termed. At the end of two hours and ten minutes from the commencement of the operation, the constriction suddenly relaxed, and the organ assumed its normal position. The patient made a good recovery, and when last heard of, was 'well in every respect.'

The question of the ability to reduce a chronic inversion of the uterus has engaged the attention of most gynæcologists, and Leishman believes that pressure with incision will succeed in any case where there are no chronic adhesions. Dr. Barnes has invented a new operation in order to avoid amputating the uterus, or of affecting 'forcible reduction' as advocated by Dr. White. The author considers Dr. Barnes' describing his operation as a 'forcible reduction' absurd, and believes that there is no conceivable method less forcible than that of making gentle elastic pressure upon the fundus, producing thereby equable moderate traction by the vagina, which in complete inversion is attracted within the os. The vagina dilates the os with less tendency to laceration than a tent. All Dr. White's cases, eleven in number, have been reduced at a single sitting without any known laceration of tissue. His most difficult cases have not been the longest in reduction, but in two where amputation had been begun and failed through some fault of the operator. Adhesions were believed to have occurred in these cases.

The writer considers any manipulation whilst the uterus is undergoing involution to be more dangerous than at a subsequent period. Dr. Evory Kennedy's dictum that reduction was possible and safe at the early stages, and impossible after a lapse of ten or fifteen years, through alteration of the tissues, was entirely disproved by his cases of reduction at the end of seven, fifteen, and twenty-two years.

MAYER ON A SUCCESSFUL CASE OF CÆSAREAN SECTION.—Dr. T. Mayer (*Archives de Tocologie*, September, 1874), relates a case in which Cæsarean section was performed on a married woman, aged thirty, about three feet high, the subject of acute antero-lateral curvature of the lower third of the spine. She would not submit to the induction of premature labour. An incision six and three quarter inches long was made on the mesial line, beginning about four-fifths of an inch below the navel, and extending to within half an inch of the pubes. A strong effort of inspiration at the moment of opening the abdominal cavity nearly protruded the whole of the intestines, which were with difficulty restrained. An incision was next made in the median line of the uterus, care being taken not to injure the bladder. The membranes had been ruptured previously to beginning the operation, and all the amniotic fluid drained off. Not a drop of blood or of liquor amnii escaped into the peri-

toneum. The sides of the wounds were well sponged with cold water to check bleeding. The membranes were then divided by means of the stylet. The placenta was removed with slight loss of blood, the hæmorrhage being checked by cold applications, and the uterus made to contract firmly. A seton was introduced through the vagina and the uterine wound, being fastened externally above the pubes. The sutures were passed through the abdominal walls only. On the sixteenth day the drainage-tube was removed. The woman recovered without any symptoms of metritis or peritonitis, or hæmorrhage. She had severe diarrhœa, and with it the left leg became affected with phlegmasia dolens.

The village and the house in which she was operated on were of the most unhealthy description. The room, however, was of fair size.

WHITTAKER ON GALVANISM IN AMENORRHOEA. Dr. James Whittaker (*Ohio Clinic*, July 25), relates a case of obstinate amenorrhœa occurring in an otherwise healthy female aged twenty-two years, in which, after all other means of relief had failed, the interrupted current from a battery of twelve elements induced the menstrual discharge. In applying the current, the positive electrode was placed over the fundus uteri externally, and the negative, a fine gold-pointed wire, was introduced within the cavity of the uterus.

W. C. GRIGG, M.D.

MISCELLANY.

DEATH OF DR. EDWARD SMITH.—We regret to have to announce the death of Dr. Edward Smith, F.R.S., assistant-medical officer to the Local Government Board. Dr. Smith held the degrees of M.D. (1843), and LL.B. and B.A. (1848) of the University of London. He was also a Fellow of the Royal Colleges of Physicians and of Surgeons. He was a man of rare mental powers combined with indefatigable industry. The mere list of his published works would occupy a considerable space, whilst it would show at the same time the varied character and the depth of his researches in various branches of medical science. In 1849 he published an *Account of a Journey through North East Texas*. He was also the author of works on *Health and Disease as influenced by Daily and other Changes in the Human System*, and on *Consumption*, and of numerous papers in medical and scientific journals, on Pulsation and Respiration, Phthisis, Prison Diet, the Action of Alcohol, Food, etc. In 1862 and 1863 he reported to the Privy Council on the dietary of Lancashire operatives, and other low-fed populations, and contributed a volume on food to the International Science Series. His most recent works are a *Manual for Medical Officers of Health* and a *Handbook for Inspectors of Nuisances*. Dr. Smith was formerly, for some years, assistant-physician to the hospital for consumption at Brompton; he was a corresponding member of the Natural History Society of Montreal, and of the Académie des Sciences et Lettres de Montpellier.

MEDIÆVAL BARBARISM IN SPAIN.—A correspondent of the *British Medical Journal*, writing from Madrid, gives an account of a few of his patients, and the course of treatment to which they had been subjected prior to having consulted him. He says that one of the prescribers of the nastinesses described is an ex-Court physician, and that another fills a professorial chair. Case 1. D. F. L., aged thirty-five, having chronic articular rheumatism, was ordered nine days' baths of archena; after that, to observe the 'Cuarentena' (or forty days); to take no medicine whatever. Being worse than ever at the end of that period, he was ordered friction all over the body with a

slush composed of equal parts of smashed earth-worms, rancid oil, and putrid mule's dung, to be applied assiduously for the mysterious nine days, night and morning. Case 2. Senora B. de L., a 'noble lady,' aged thirty-two, recently confined, had a small abscess of the left breast. She was attended by an ex-Court physician, who, when he had exhausted all his remedial skill, ordered a poultice three times a day of white pigeon's dung, saying that if that did not cure her nothing else would. Case 3. Dona Francena A., aged twenty-three, had been treated for dyspepsia with amenorrhœa for ten months. Her last prescription was 'nine days' poultices of fresh human excrement. She could only endure this disgusting barbarism two days. Case 4. Eulogia G., a servant-girl, aged nineteen, had chronic diarrhœa, and was ordered to take a tumblerful of child's urine every morning, fasting, for nine days. She could take such a dose only three days. Case 5. Pablo Insari, aged thirty, plasterer, had had six months' doctoring for heart-disease following rheumatism. The last prescription was a newly killed pigeon split open down the middle, and applied over the left chest for 'nine days,' and to go to work. Case 6. Senor Don M. H., mine-proprietor, aged thirty-nine, had cardiac dropsy. His last prescription was, a sheep to be killed daily, and the skin, with the wool on, to be wrapped round the body tightly. Case 7 is perhaps the most ridiculous of all. Miss S. A., an American lady, sent for me, and said, 'Doctor, I've got the gripes for the last two or three days, and yesterday, feeling no better, according to a notion in my country (Pittsburg), I took eight or ten black pepper-corns, wrapped up in a piece of your *London Times* (they must be swallowed in printed paper). I guess that they have stuck somewhere, and I feel awful bad, and I want you to give me something right off to get me rid of them pepper-corns and your English paper. Had I only got the *New York Herald* they would have gone slick down.' A small dose of castor-oil shortly set her right. By way of confirmatory evidence, our correspondent gives the following literal translation of a paragraph in the *Correspondencia* journal: 'In the slaughter-house of Madrid, which is under Government supervision, there is being committed a repugnant abuse, which, for the sake of health and public decency, and at the request of many persons, we denounce to the Senor Alcalde, chief civil magistrate of this city. In the above-named establishment, they consent or permit the sick, with arms and legs at times full of ulcers and wounds, to lie inside the carcasses of animals while hardly yet dead. Apart from the horror and disgust which this produces in the persons that witness these things, it might produce disastrous effects on the public health, and we doubt not that such scandalous acts will have an efficacious and prompt correction. We shall be on the lookout about this matter.'

DR. SYMPHORIEN CHAMPIER, THE MASTER OF MICHAEL SERVETUS.—The Rev. H. Tollin, of Schulzen-dorf near Lindow, communicates an interesting article to Virchow's *Archiv*, Band lxi. Heft 3, on Michael Servetus, executed at Geneva in 1553; and remarks that this celebrated Spaniard, who represented the principle of free and independent investigation in the later period of the Middle Ages, was accustomed to own scarcely any man as his master, and was wont to represent himself as self-taught (*auto-didakt*) in every branch of knowledge. We know, however, that Anghiera taught him his 'humanities'; Alciat, jurisprudence; Paulus Burgensis, theology; Capito, cabalistic lore; Sebastian, Münster, geography; Peter Apianus, mathematics; whilst Jacobus Sylvius, Winther of Andernach, and Fernel, were his teachers in medicine. However, save and excepting Our Saviour, whom he repeatedly acknowledged as his special teacher, Michael Servetus only publicly and expressly recognised one master amongst all who lived in his times, and that one was the surgeon Symphorien Champier, of Lyons. 'Ut pro Symphoriano Campegio, cui ut discipulus multa debeo, aliquid scriberem,' says Servetus, in the dedication of his *Brevissima Apologia*, etc. It was Champier (variously

known as Campegius, Campèse, Piercham, La Faverge, and Théophraste du Mas) who gave to the fugitive Spaniard a new home in Lyons, converted the miserable corrector of proofs into a celebrated physician, made the wild enthusiast a sensible and learned man, inspired the declared enemy of all philosophy with such glowing love of Plato in the guise of Neoplatonism, as marks a new era in the mind of Servetus and changed the whole course of his thoughts. Thus, indirectly, we owe his [partial] discovery of the circulation of the blood to Champier; for Servetus, but for this and for him, had never been a doctor; and, in one sense, Champier may be said to have brought him to the scaffold, for, had Servetus never adopted Neoplatonism, the *corpus delicti*, his *Restitutio Christianismi*, would not have appeared. We know but little of Champier, except that he was born at Symphorien le Chateau, near Lyons, in 1472, and died at Lyons in 1539. After studying surgery at Paris and Montpellier, he practised in Lyons, and after 1509 followed Duke Antony of Lorraine in all his campaigns as surgeon-general. He was knighted at Marignano, on the field of battle, and in the same year (1515) was made one of the Faculty of Medicine of Pavia. He married a relative of the celebrated Bayard, and settled once more at Lyons, where he was held in high esteem till driven away by famine-riots. Returning in 1533, he became the founder of the celebrated Collège de la Trinité, and raised the Lyons medical faculty to high position by the force of his genius, though it was not formally constituted till the year 1576. [See Perneti, part ii. *Biographie Universelle*, art. Champier, and elsewhere.] Mr. Tollin considers him as representing the civilising function of the state, or secular power, as opposed to ecclesiastical authority, especially that of the titular archbishop. Champier was a friend of Bayard's, and wrote his life. His writings appear to have been very numerous; every year, at least, a new book appeared, though it seems, like Dumas, that he often put his name to the works of others. Whatever the value or originality of his writings may have been, for on this point opinions differ, it is almost certain that he far excelled his contemporaries in the practice of his art; and one of the best of them, the celebrated Jacobus Sylvius, affirmed that in his scientific journeys he had found only two men worthy to be called doctors of medicine. One of them was Hieronymus Montuus, Servetus' friend; the other was Symphorien Champier, the teacher of Servetus.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17s. 4d.; free by post, 19s. 6d.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & CO., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The First Volume, containing upwards of Two Thousand Articles abstracted and compiled by a staff of Fifty Hospital Surgeons and Physicians, is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for the year 1873 are also ready, price 1s. 6d. each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & CO.—Calcutta: THACKER, SPINK & CO.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & CO.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & CO., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S.W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, NOVEMBER 25, 1874.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

CLINICAL LECTURE ON FIBROUS ANKYLOSIS, CHRONIC SYNOVITIS, ETC. BY LEWIS A. SAYRE, M.D., OF NEW YORK.

GENTLEMEN: The first case that I bring before you to-day is this girl, who has been suffering for some time from fibrous ankylosis at the hip-joint.

This form of ankylosis in many cases very closely assimilates bony ankylosis. It is important, therefore, that you should be able to distinguish one from the other with great certainty, for the management of the two conditions is conducted upon entirely different plans.

In those cases which most closely assimilate bony ankylosis—for it is in such that differential diagnosis is most difficult—if movements be made at the joint, and any motion whatever be secured during the manipulation necessary to a thorough examination of the case, it will be followed by more or less of pain within twenty-four hours. This is a distinguishing feature of cases of fibrous ankylosis; for, when bony ankylosis is present, no movements at the joints can be made, consequently pain will not be produced at the point of ankylosis. This rule you will find to be reliable. The subsequent occurrence of pain in and about the joint, even if there be no apparent motion, will justify you in resorting to measures calculated to give to it gradual restoration of motion.

In the case of this little girl, it was exceedingly difficult to determine whether any motion whatever was remaining at the hip-joint, so firmly flexed and adducted was her limb. But the day following the manipulation considerable pain was present, and other evidences of inflammatory action were quite well developed. The limb was kept at perfect rest by placing the child in bed. By the rest in bed, and continued application of cold to the inflamed parts by means of icebags, an extension in the line of deformity gradually changed towards the normal. All inflammatory action was subdued within a few days, and then she was placed upon this instrument, which had been specially devised to meet the indications in her case. The instrument consists of a pelvic belt, with perineal bands: a long bar with a foot-piece and adjustment for extension; a knee-cap; and a movable joint opposite the hip for flexion, extension, and abduction. At the movable joint, arrangement is made so that, by means of screws, abduction and rotation of the limb outwards can be effected at the same time. It is, in short, a modification of Taylor's long splint, the modification consisting in the use of screws for obtaining abduction and rotation. It has now been one month since the instrument was applied, and the change which has been produced during that time is very marked. The limb has been abducted to such an extent that

it is now nearly parallel with the opposite limb. This can be ascertained only by placing the pelvis in a fixed position. Rotation has been almost perfectly restored, and flexion and extension have been restored to considerable extent. Abduction and adduction are quite free, and the limb is upon the highway to complete recovery.

The case well illustrates what extraordinary results can be obtained in the way of overcoming muscular rigidity by the application of a constant unremitting force. Under circumstances favouring the application of constant unremitting elastic force, equally as favourable results can be obtained by paralyzing muscular power, thus overcoming deformities produced by it.

The second case is one of chronic synovitis. This patient, as you see, is a man of medium size, exceedingly muscular, and forty years of age.

Some seven or eight years ago, while wrestling, his foot caught against the edge of a board in the floor, which was slightly elevated above the others, and the quadriceps muscle being placed in a condition of powerful tension, luxated the patella upon the right knee inwards, and he fell. While he was attempting to raise himself, the muscle restored the patella to its proper position. For a few days he was unable to walk, but in a short time recovery, as was supposed, was complete.

About two years after the occurrence of this accident, chronic inflammatory action was set up on the opposite knee, and soon affected both knees; they gradually increased in size, and now, as you see, they are immense. One measures eighteen, and the other seventeen and a-half, inches in circumference, and the calves of the legs are very much diminished in size.

For the last two years this condition has remained about stationary. The effusion is now so abundant that the patella of each knee is lifted from its articulation, and, as pressure is made upon it, it can be made to strike the bones below with an audible click. By transmitted light a lake of fluid can be seen below the ligamentum patellæ, with a large collection of semi-gelatinous material at its upper surface, presenting a very beautiful pathological appearance. These knees have received an almost endless variety of external applications, and his general system has received a great amount of medication, but all have failed to produce any change, and we now find them as they have remained for a number of years.

The effusion in this case has become so great as to preclude all possibility of its removal by absorption, simply because the excessive tension that has been made upon the absorbents has paralysed their action in such a manner that absorption cannot take place.

The condition is analogous to that occasionally seen in ascites, when the pressure is so great from accumulated fluid that the absorbents will not respond to the influence of internal remedies. In that case, the removal of only a small portion of the fluid will in many cases reduce the tension sufficient to permit the subsequent removal of the remainder by the renewed action of the absorbents. This case, however, has been of so long standing that it is not probable that the removal of a portion of the fluid would be of any benefit, even though followed by the most constant and powerful compression.

In most cases, particularly in the subacute and earlier chronic stages, decided benefit can be obtained by pressure applied to the joints. This

can be conveniently and effectually done by means of compressed sponge. Cover the joint which is the seat of the synovitis with compressed sponge, and retain it in position by means of a roller bandage. The sponge is then wet with warm water, which causes it to gradually expand and thus produce an equal amount of pressure over all the parts covered; and it can be kept up as long as may be desirable. The sponge can be applied once or twice a day, according to the necessities in the case. Changing it every twenty-four hours is usually sufficient.

The question now arises, What is the best thing that can be done for the relief of the present condition of this case?

A free incision will permit the fluid to escape, but the risk of exciting an uncontrollable inflammatory action would hardly warrant such a procedure.

What I propose to do in this case is to remove the fluid by means of the aspirator. This, also, is not altogether a safe operation, for inflammatory action may follow its performance; but, under the circumstances, it is the best operation that can be resorted to. In such a case as this, a certain amount of risk must be taken, no matter what operative interference may be adopted.

In all probability, simple aspiration will fail to give any permanent relief, for the reason that the case has been of so long duration. It is also altogether probable that the synovial membrane has become changed in its anatomical structure to such an extent, that permanent benefit will only follow the adoption of some more active measure.

There is a chance, however, that the simple operation of aspiration, followed by elastic pressure, such as obtained by the use of compressed sponge and a roller bandage, may accomplish a cure.

If simple aspiration do not succeed, the fluid will then be removed by means of the ordinary trocar; and after its removal, the cavity will be injected with Lugol's solution of iodine. This principle of treatment is precisely the same as that which governs us in the treatment of the tunica vaginalis in cases of hydrocele; namely, to excite a new action in the old and changed membrane, by means of an irritating agent; and for this purpose the solution of iodine indicated is much the safest agent to be employed.

In either case the patient will be placed in bed immediately after the operation, the knees will be firmly bandaged, locked in a perfectly immovable apparatus, elevated above the level of the body, and perfect rest maintained. In addition, icebags will be constantly employed if necessary. The object is to retain the inflammatory action just within the point of danger. In this manner we may reasonably expect to bring about complete recovery.

The next case is one of cancer of the lower lip. These growths, seen not infrequently upon the lower lip, are usually regarded as cancerous in nature. Some of them are not. Some of them bear so close a resemblance to the ordinary epithelioma of the lip, that they cannot be distinguished from each other by the naked eye. They are usually the result of constant and long-continued irritation.

Fortunately, there is one plan of treatment best adapted to them all. Remove them with the knife, and that makes an end of them.

There are some steps in the proceeding which are necessary to be observed if you would make a nice operation, and one which will prove satisfactory to

your patient. The ordinary operation is to remove the diseased mass, by making a V-shaped incision, large enough to embrace the whole of it.

Serious hæmorrhage can be avoided during the operation by having an assistant to make pressure upon the facial arteries as they pass over the ramus of the lower jaw. The wound can be closed by means of sutures, or pins with the figure-of-8 suture. I commonly employ the pins. These are to be passed through the lips of the wound, and then its edges are brought together in such a manner as to avoid leaving any notch in the free margin of the lip. The attachments of the cheek may be loosened with the knife if necessary, in order to give more opportunity for perfect adjustment. Two pins are usually sufficient. After the pins have been adjusted and the sutures twisted about them, do not neglect to place a piece of adhesive plaster beneath the point of the pins to prevent irritation and excoriation. Next, long narrow strips of adhesive plaster are to be adjusted in a manner to give support to the pins in holding the lips of the wound in coaptation. These strips, passing above and below each pin, should be carried far back upon the sides of the face and neck. Carefully adjust the edges of the wound a second time, as the plaster is carried over them. The pins are to be removed within forty-eight hours at most after the operation. To do this without disturbing the wound, seize the pin at the head with a pair of pincers, and carefully turn it round once or twice before making the least traction. With this precaution the pins can be withdrawn without disturbing the threads or plasters, which together with the crust, are left remaining, and should not be removed for some time. Unless the pins are removed before ulceration and suppuration have been established about them, scars will be left at the points of insertion and exit; but with this precaution scar can be avoided.

Here, gentlemen, is a case which belongs to the every-day practice in surgery—one of ingrowing toe-nail. It is important, therefore, that you should understand how to manage successfully such little cases. Almost any one can cut off a limb, but it is not every professed surgeon even who successfully manages these painful cases of ingrowing toe-nail. It is quite fashionable, especially in cities, to recommend these people to go to some *specialist*, who 'knows all about corns, toe-nails, etc. ;' and one of these cases is scarcely ever met here but what has been more or less treated by that class of men. Narrow-soled shoes and boots are the great prolific sources of this difficulty. A great many people imagine—and we are sorry to be obliged to say that the greater proportion of this class is made up of ladies—that a narrow foot and high instep are elements of beauty. The result, however, of these efforts to distort the foot is, the toe-nails cut their way into the tissues, and the tissues become hypertrophied. The appearance very commonly presented is a large mass of fungous granulations rising up from the side of the nail, as you can see very well illustrated in this case.

The toe cannot be cured until this redundancy of flesh is gotten rid of. Sometimes it becomes necessary to employ the knife in the removal of this superfluous growth. Nitric acid is a very good application, and nitrate of silver is another.

Immense relief can be afforded by applying a few threads of cotton beneath the cutting edge of the nail, in such a manner as to protect the excessively

tender tissues from the irritation produced by being crowded into contact with it. When the cotton is properly applied, pressure upon the ball of the toe will give no pain. The proper instrument with which to apply it is a narrow thin knife-blade without cutting edge. With this instrument draw a few threads of cotton down between the nail and the mass of granulations, and so on until they are carried beneath the cutting edge of the nail. This operation will give some pain during its performance, but the relief which will be afforded by it will be most marked. After the application of the cotton, pencil the fungous granulations over freely with nitrate of silver, or with whatever may be used for the purpose of destroying them. Repeat the application as often as the destroyed tissues separate, until the exuberant growth is all destroyed.

The next case I present to you, gentlemen, is one of considerable interest. This man first suffered from a fracture of the forearm. Phlegmonous erysipelas attacked the limb a short time after the accident; and you will here notice the many openings which have been made for the free escape of pus, numbering, as the house-surgeon says, thirteen. The wrist-joint has also become involved in the inflammatory process. The case was once set down for amputation, but I resolved to make an effort to save the limb.

The difficulty involving the wrist-joint was the chief obstacle to be overcome. The thing desired was to place the joint perfectly at rest, and at the same time remove all pressure from the articular surfaces. How was this to be done? Take a piece of sole-leather, long enough to reach from the digital extremity of the palm of the hand to near the flexure of the elbow, and wide enough to half or two-thirds surround the arm. Dip it in cold water, and make it thoroughly flexible. Cover it with a piece of adhesive plaster, plaster side out, long enough to go completely around it lengthwise, and lock. Now, having covered each opening with a piece of oakum, apply the leather-lined plaster to the palm of the hand, mould it, and secure it with a roller-bandage as far as the wrist. Having arrived at that point, grasp the hand already covered, while an assistant grasps the arm near the elbow; then making extension and counter-extension, until the patient tells you that all pain is relieved, bring the remainder of the leather-lined plaster against the forearm and secure it with a continuation of the bandage. In this manner all pressure is removed from the articular surfaces, pain is relieved, and an apparatus is afforded which retains everything at perfect rest. It is almost impossible to devise any means for meeting the indications in this case which is simpler than this. The leather is much better adapted to such uses than a board, for the reason that it can be more perfectly moulded to all the inequalities of the limb. The plaster lining holds it securely in position, in such a manner as to prevent slipping. Since the application of this splint the œdematous condition of the limb has passed away, and the question of amputation is no longer present for consideration.

PREVENTION AND TREATMENT OF PUERPERAL DISEASES. BY DR. GOODELL, OF PHILADELPHIA.

[The following paper, extracted from the American Supplement to the *Obstetrical Journal of Great Britain and Ireland*, seems worthy of being

read by the general profession, as embodying views and actions exceedingly novel and successful on a most important practical subject.]

The Preston Retreat is a small lying-in hospital for reputable married women. The yearly average has thus far been about one hundred labours, but it is now rapidly increasing. It contains four wards, each with a capacity of 9,153 cubic feet, and each furnished with five beds, of which not more than four are generally occupied at one time. The ventilation in winter is obtained by the escape of the cold and foul air through an old-fashioned fireplace, in which a jet of gas is kept constantly burning, and by the free admission of pure air, which has been heated in the basement by passing around steam-chests, with large radiating surfaces. In summer, the admission of pure air depends exclusively upon open doors and windows, and the ventilation is, consequently, less perfect than in winter. In the spring and autumn months there are many days in which the temperature is too warm for the free admission of heated air, and yet too cold for open windows. These are, therefore, the two seasons of the year which I dread the most, and in which I avoid, as much as possible, crowding the wards.

The wards are used invariably in rotation. By close management, and by crowding walking patients together, one of these wards in its turn stands idle for two or three weeks. During this time the doors and windows are kept open. Before it is again occupied by patients, the walls, floor, woodwork, and furniture—all of which are painted—are thoroughly scrubbed with carbolic acid soap, and then mopped over with a solution of half a pint of carbolic acid (Calvert's No. 4), to one pail of water. From this time until the ward is again vacated, no portion of it, not even the floor, unless accidentally soiled, is touched with water.

The nurses wear such clothing only as can be washed. As soon as the inmates of a ward are well enough to take care of themselves or of one another, their nurse is relieved from duty. She now takes a soap bath, puts on an entirely clean suit of clothes, and goes into a ward which has been thoroughly ventilated and cleansed. Before a new batch of patients falls to her care, she has had one week or more of rest. I visit the wards thrice daily, beginning always with the ward last occupied, and with the patient last delivered. Whenever a vaginal examination is needed, it is put off until all the other patients have been seen. The examining finger is then anointed with an ointment containing carbolic acid, and the hands are afterwards washed with carbolic acid soap. *Post mortem* examinations I never perform. Whenever one is needed, an expert is called in, and remunerated for his services.

The beds consist of a tick filled with fresh straw and covered with an army blanket. After the discharge of a patient, her bed is emptied, and the tick, blanket, and bed-clothes are boiled in water to which a little carbolic acid has been added. Each bed is furnished with a feather bolster and pillow, which are exposed, on slats to the air when not in use. Once a year every bolster and pillow-tick in the house is washed, and the feathers baked and 'renovated,' as it is technically termed. They also pass through the same process whenever soiled, or whenever used by a patient whose convalescence has been delayed.

The patients come chiefly from the poorest classes; but many in more comfortable circumstances, with

the hope of getting better care, seek admission on account of some difficulty attending their former labours. On this account, the proportion of difficult labours is much above the average. Those patients who have families often put off coming in until labour has actually begun, and then leave at the earliest possible moment. Notwithstanding this, since patients have the privilege of remaining four weeks after their delivery, the average stay of each one is sixteen days before delivery, and eighteen days after. Every patient, upon admission, takes a warm bath, and at least once a week thereafter before her delivery. If she exhibit signs of feeble health, she is at once put upon the use of quinia, and of the house mixture, consisting of two parts of the muriated tincture of iron, with three of dilute phosphoric acid. The habitual constipation of pregnancy is met by the administration, either in the morning of a teaspoonful of pulvis glycyrrhizæ compositus of the Prussian Pharmacopœia; or, at bedtime, of four Lady Webster's pills (pilulæ stomachicæ). When a more active purge is needed, the compound jalap powder or the compound cathartic pill (U. S. P.) is given. Headache and sleeplessness are treated by warm baths, by full doses of potassic bromide, and by the above-named medicines, when indicated; albuminuria is dealt with in pretty much the same way, but always with iron and phosphoric acid. The regular diet is plain and wholesome, yet more liberal than is usual in charitable institutions. Apart from the frequent use of aperients, a relaxed condition of the bowels is promoted by serving table-syrups at every meal, by fruits—fresh or dried, according to the season—and by all such vegetables as can be eaten raw, viz., lettuce, cress, radishes, leeks, onions, tomatoes, cucumbers, and cabbages. Of these, in this latitude an ample supply is obtainable during nine months of the year.

When a patient falls into labour, she first has her bowels moved by an injection, and then takes a warm bath. The bag of waters is usually ruptured artificially, and the liquor amnii collected in a grocer's scoop. The second stage of labour is never allowed to linger; any delay is met by the use either of the vectis or of the forceps. As soon as possible after the birth and the removal of the child, the placenta is delivered by Credé's method. I may here remark that the still pulsating cord is first cut, then 'stripped' of its blood, and as much as possible of its gelatin, and finally tied, when it has ceased to bleed and has become flaccid. Neither belly-band nor any kind of dressing is afterwards applied, but the cord freely dangles about from the navel. Treated in this manner, it dries up without any bad smell, and falls off like a ripe fruit, without leaving a raw stump. Out of more than five hundred infants treated thus, not one has had a pouting or sore navel requiring treatment, and not one has had an umbilical hernia. I am also well satisfied that, by dispensing with the belly-band, I have had fewer cases of inguinal hernia. Those of my readers who wish a more detailed account of this method of dealing with the cord, can consult the *American Journal of Obstetrics*, vol. iii. p. 327.

Ergot is hardly ever resorted to as an oxytocic; but one teaspoonful of the fluid extract is invariably given as soon as the head presses upon the perinæum. When the labour is over, the perinæum is examined, and, if torn, is at once sewed up with silver sutures. The patient is now washed clean, and a binder and

cylindrical compress applied, the latter in the hollow just below the fundus of the womb. The bedstead on which she has been delivered is next wheeled from the delivery-room to a ward and placed along the side of a bed, to which the woman now hitches herself over. Contrary to the generally held opinion that absolute rest after labour is indispensable, in no single instance has this muscular exertion apparently brought about a flooding. It seems rather to condense still further the uterine globe. Very rarely, indeed, has a flooding happened outside of the delivery-room. However warm the weather, a blanket is thrown over the patient, and a foot-warmer put to her feet. These remain until reaction sets in and she asks to have them removed. A mug of beef-tea made from Liebig's extract is now given, and the child is put to the breast as soon as it will take it. Thereafter, in a natural convalescence, the woman gets tea, boiled eggs, bread and butter, for breakfast; potatoes, and some kind of meat, for dinner; stewed or fresh fruits, tea, bread and butter, for supper. On the morning following the day of her labour, the binder is removed for good, and she slips into a chair while her bed is making. This is repeated once or twice a day until the fourth or fifth day, when she, if so disposed, gets up and dresses herself. No patient quits her bed against her will; yet the force of example is so great that very few care to stay in bed, when they see their companions up and about.

No woman is allowed to suffer from after-pains. Whenever these are complained of, quarter-grain doses of morphia are administered every hour until relief is obtained. In stubborn cases of after-pains I have found nothing act so promptly as the administration of ten grains of quinia every six hours, until the ears ring. For this valuable suggestion, I am indebted to my friend Dr. Fordyce Barker. Bed-pans are not employed, except in cases of illness, or in cases requiring vaginal injections; but each woman has her own chamber-pot, which she uses indifferently, either in the sitting or the knee-elbow posture. Every woman is required to wash her own person at least once a day, and that with carbolic-acid soap and a wad of fine oakum, which is at once thrown away. Only under very exceptional circumstances does the nurse cleanse the patient. Should the lochia become offensive, the woman is made to get out of bed and slip into a chair three or four times a day. This usually corrects the fetor; but if it do not, then, and only then, is a solution of potassic permanganate thrown up into the vagina. Firmly believing the nozzle of a syringe to be the medium of communication of virus from patient to patient, I avoid the use of vaginal injections as much as possible. For a like reason, the temperature thermometer is not habitually used, but only in single cases as an aid to diagnosis.

Whenever the lochia are offensive, or the pulse is over 90, or the thermometer indicates a temperature higher than natural, or pelvic pains are complained of, or, in short, whenever any untoward symptom appears, quinia is given in from six- to ten-grain doses every four hours, until the ears ring. In addition, for abdominal pains large doses of morphia are given, and the whole belly is painted with iodine, and covered with a mush-poultice. The canonical purge on the third day is dispensed with. A patient has usually a movement of the bowels either before or on the day in which she gets up for good. If this does not happen, she takes four Lady Webster's pills at bedtime, which then act on the morning of the

sixth day. As soon after getting up as she feels strong enough, she takes a warm bath.

Thus far I have stated the means adopted at the Preston Retreat for the prevention and the treatment of puerperal diseases. I now propose to give my reasons for such of them as need some explanation.

But few words are needed to explain why the ordinary chamber-pots are used, and why patients are made, once or twice a day after the first, to get out of bed and slip into a chair. The presence of putrescent fluids in the utero-vaginal tract is recognised by all writers as the great cause of the autogenetic variety of puerperal disorders. But the recumbent posture of itself necessarily tends to detain these poisonous discharges in contact with the traumatic lesions of labour. These discharges may also be partly imprisoned in the vagina through the swollen condition of the more external soft parts, or partly corked up in the uterine cavity by the presence in the cervical canal of a putrid clot. In such cases detergent vaginal injections are highly recommended. But clinically they will be found of limited value; for they cannot reach high enough, and do not ordinarily dislodge a large clot even when situated low down. True, intra-uterine injections are not open to one of these objections; but, apart from their being attended at best with some degree of hazard to the patient, the operation is too delicate a one to be intrusted to a nurse. Besides, in hospital practice the nozzle of a syringe—to say nothing of the fingers of a nurse—is, I fear, so often one of the vehicles for the transmission of virus, as to make this means of disinfection of doubtful propriety. In a local outbreak of fever, especially of the diphtheritic form, I should, however, suggest the use, immediately after labour, of vaginal injections containing the nitrate of silver or the persulphate of iron, in quantities large enough to sear over the traumatic lesions of labour. Such injections I have had no occasion to try, but they ought to inhibit active absorption and promote healthy granulation.

While seeking a substitute for the syringe, my attention was directed to the fact that the act of sitting on the ordinary chamber-pot often forced out putrid shreds or fetid clots, which had not been washed away by vaginal injections. This led me to discard, except in cases of positive illness, the use of bed-pans or of any other utensil—such as urinals—which can be used by a woman when lying on her back. Shortly after making this change, I found that, for like reasons, some shrewd and very practical writers of the last and the present centuries urged an early departure from the recumbent posture. Further, a residence of some years in the East had taught me that Oriental women, at least, can with impunity get up and be about a few hours after delivery. Influenced by these facts, I decided, cautiously at first, to introduce into the wards of the Retreat a system of puerperal gymnastics, consisting in no restraint whatever as regards the position in bed, and in the daily release from an irksome confinement. I was much pleased to find that the muscular exertion needed for these movements, so far from inducing hæmorrhage, excited the womb to contraction, and emptied it and the vagina of their putrid contents. I can testify that whenever the lochia are offensive, these upright positions, repeated several times a day, are excellent deodorants, better in fact than any detergent vaginal injections. There is yet another

advantage gained by this plan; it affords, in hospital practice, an excellent opportunity for bundling the bed and bedding out of the ward and giving them a much-needed airing. In a crowded hospital-ward, the hygienic importance of such repeated disinfection can hardly be over-estimated. At the risk of being called an enthusiast, I will go a step further, and hazard the assertion that here is a form of puerperal septicæmia not necessarily accompanied by putrid lochia,—at least not appreciably so,—but indicated by high temperature, rapid pulse, complete anorexia, heavy sweats, and, later, by herpes labialis, which stubbornly resists treatment until the patient is made to get out of bed. This I have seen often enough, after keeping a woman on her back for some pelvic disturbance, to prevent any mistake as to the relation of cause and effect.

Lying-in women are encouraged to get up for good when they feel so disposed, because there are, to my mind, strong objections to the rigorous maintenance of the recumbent posture. Labour is, in general, a strictly physiological process, and there can be no sound reason why it should be made to wear the livery of disease. Nature teaches this very plainly, for most women wish to get up long before their physicians are willing to let them. The fact of a woman's wishing to get up is to me a very good reason why she should get up. In the second place, few physicians will deny that nothing so relaxes the tone of muscular fibre as a close confinement in bed. In my experience a woman ordinarily feels stronger on the fifth day than she does on the ninth, if rigorously kept under quilts and blankets. Once more: the upright position not only excites the womb to contract, but, by distributing the blood and equalising the circulation, it actually lessens the amount of the lochia and shortens their duration. On the other hand, the dorsal decubitus keeps up a passive congestion of the womb as a whole, the engorgement of the greatly hypertrophied placental site, and a blood-stasis in the now thickened posterior wall,—all important factors in hindering the process of involution. Again: uterine diseases are hardly known among those nations whose women early leave their beds. From passages in the writings of the classics, it is evident that among the ancient Greeks and Romans, those models of physical strength and beauty, the women arose and even bathed in a running stream very shortly after delivery; in some cases, on the very day. Finally: what is sounder than all theory, a sufficiently long and well-sifted experience has proved to me that, by such a treatment, convalescence is rendered far more prompt and sure. At this result, very unexpected to the multiparous patients of the Retreat, they are constantly expressing their surprise.

(To be continued.)

PELLIZZARI, TOMMASI, PERRONCITO, LEWIS, COBBOLD, AND GIACOMINI ON CYSTICERCERCI.

(Concluded from page 691.)

Having demonstrated the fallacy of the propositions advanced by Perroncito in regard to the actual amount of heat necessary for the destruction of cysticercæ, Pellizzari next attacks the question as to the cause of the prevalence of tapeworm. In this view he first adduces some interesting data that had been previously communicated to the Medico-

Physical Academy of Florence by Professor Marchi. On the occasion referred to, Marchi had stated that out of thirty-five *tænia* which he had examined, only one belonged to the species known as *tænia solium*; all the other thirty-four being of the unarmed type, or *tænia mediocanellata*. Reflecting on this very striking fact, and also on the circumstance that he had in vain begged his colleagues to send him specimens of *tænia solium*, Marchi seems to have missed the very palpable explanation of this otherwise strange phenomenon. 'How does it happen,' exclaimed Marchi, 'that, notwithstanding the occurrence of 13,000 measled hogs in the public butcheries, I have seen but one specimen of *tænia solium*, whilst thirty-four cannot have originated from the pig?' 'The wherefore is obvious enough,' replies Pellizzari; 'because our hygienic regulations demand that the flesh of the hogs be raised to a temperature of 60° Cent. (140° Fahr.);' and he then himself immediately proceeds to ask another question, namely, as to how it happens that the *tænia solium* is so frequently seen in other places. To his own question, Pellizzari responds by remarking (1) that there are not so many precautions (of a sanitary kind) taken in other places, and (2) that the people elsewhere consume more slightly salted or uncooked meat, as sausages and so forth (*come salame giovane, saliccia e via dicendo*). Pellizzari, having explained that Marchi's thirty-four tapeworms must all have arisen from the consumption of the cysticercus of the ox, then goes on to speak of the prevalence of tapeworm in Florence, even in little children. This last named feature, he says, is due to the circumstance that raw meat is frequently employed as a restorative (*come cura ricostituente*). 'Thirty years ago, remarks Professor Pellizzari, 'it was just as difficult to find a single *tænia mediocanellata* as it is now easy to find a great number of these worms; and all because it is now-a-days customary to eat the flesh of the ox, either insufficiently cooked or raw. This absolute inversion of the facts of the case affords proof of the correctness of the position sustained by me, to the effect that the cooking of meat up to the degree of temperature necessary for ebullition, ensures the destruction of the cysticerci.' Notwithstanding this statement of his own, Pellizzari thinks that the interference of inspectors may be pushed too far, and thus serve to bring about the very disasters which it should be their supreme object to prevent. Thus he argues against the suggestions of those who would entirely prevent the sale of measly meat, and who would only permit, as obtains in the province of Modena, the melting down of the fat of hogs. Very strict measures of this sort would, as he says, constitute a radical means of entirely stamping out *tænia*, but he also very judiciously reminds the sanitarian (*igienista*) that 'such a step would be a serious thing for the tradesman, bringing injury not only to the municipal administration, but also proving an encouragement to smuggling. In this way the public health would sustain worse injury by the inducement held out to the owners of infected animals to slaughter them in secret butcheries; thus little by little withdrawing the meat from the superintendence of the public officials. By the adoption of fraudulent measures there would be a daily consumption of diseased meat; and thus also, while the public administration would suffer loss, the public health, on the other hand, would gain nothing?' In effect, Pellizzari says, if we advise the employment

of more severe and radical measures than those already in vogue in Florence, we should overburden the tradesman, almost compel him to defraud the exchequer by smuggling, and greatly injure the public health.

The facts and explanations advanced by Italian writers regarding the causes of the endemic prevalence of tapeworm, are in perfect harmony with those we had earlier obtained from other sources. Respecting these causes much has been written that need not be repeated, but some of the facts recently brought forward by Cobbold in his manual of the internal parasites of our domesticated animals, are both new and interesting. The eighth annual report of the sanitary commissioner of the Government of India had already made us acquainted with the fact that during the year 1869, out of 13,818 head of cattle slaughtered in the stations of the Upper Punjab, 768 beasts were found to be infected with measles-cysts. This, as Cobbold remarks (Tommasi's edit., p. 54) 'affords a rate of 5.55 per cent., being a considerable diminution of the proportion observed in 1868, when the percentage gave a total of 6.12. The reduction was without doubt due to the vigilance and enlightenment of the army meat inspectors.' The prevalence, however, of tapeworm does not bear relation to the number of animals infested with cysticerci so much as to the actual number of cysticerci developed in infected animals. Cobbold has frequently pointed out the inadvisability of condemning and burying the carcasses of measly oxen, whether there be few or many cysticerci present, and he has stated, on trustworthy evidence, that even the presence of a few cysticerci is deemed by some inspectors a sufficient reason for rejecting the entire animal. Such a waste should never be allowed. In regard to the numbers of ox-measles present in particular instances, Cobbold also adduces some remarkable facts privately communicated to him by Dr. Joseph Fleming, of the Indian Army Medical Staff. 'None of our experimental animals,' he says, 'though fed with scores of ripe proglottides, yielded such an abundance of cysticerci as Dr. Fleming encountered in the Punjab cattle. In one pound weight of the *psoas* muscles he counted no less than 300 cysticerci.' From this it follows that the flesh of any one largely infested animal is capable, under the favouring circumstances of ration distribution and imperfect cooking, of giving rise to the formation of numerous tapeworms. Some people, including not a few of the profession, make light of the occurrence of tapeworm, and we have seen patients who have been told that the presence of the worms was of little consequence to them. For this wide-spread error, there is some basis in the fact that by far the majority of infested persons suffer only the trifling inconvenience arising from the passage *per anum* of the proglottides; moreover, the less civilised the tapeworm-bearers happen to be, the less are they likely to suffer. The often quoted experiences of Raschin, as related by Leuckart, where 500 hospital patients, in the Baikal district, had tapeworm, although all were being treated for other disorders, affords another argument tending to produce the same conclusion. On the other hand, amongst Europeans a small percentage of patients thus infested, suffer severely. But without trenching upon the symptomatology and prognosis of tapeworm disease, we may further observe that Cobbold has summarised the whole facts of cysticercal prevalence within the compass of two

brief propositions. 'The prevalence or the rarity of cysticeri in cattle in any given country must be determined primarily by the habits of the people; for since the beef-measle can only result from the ingestion by the ox of the eggs of the *tænia mediocanellata*, it is clear that the degree of infection of cattle will correspond with the facilities offered for egg-dispersion. In like manner, it may also be affirmed that the frequency of this particular species of tapeworm amongst the people occupying any given area will bear a strict relation to the amount of underdone meaty beef consumed by the inhabitants' (Tommasi, *loc. cit.* p. 48; *Manual*, p. 37). But another question, and one of great interest to sanitary science, is that which Cobbold has raised in reference to the period that nature requires for the destruction of the cysticeri, or, in other words, for the performance of a natural cure by calcareous degeneration of the parasites. He has shown that all kinds of tapeworm larvæ (measles, bladder-worms, cœnuri, and so forth) have a natural life-epoch assigned to them, and in one of his experiments on a Dutch heifer or young cow he demonstrated that a period of ten months was more than sufficient to insure the perfect destruction of the cysticeri of cattle. Moreover, this law or process of natural cure is not limited to cestode parasites, but affects all other kinds of internal parasites in one or other of their juvenile stages of growth. In the flesh of his experimental animal, Cobbold estimated that there were not less than 12,000 of these degenerated cysticeri. This positive contribution to our knowledge of the limits assigned by nature to the epoch of larval activity, is not merely of abstract scientific interest, but it has important practical bearings inasmuch as it points out in what way an entire herd of cattle (known to be measled by the *post mortem* examination of one animal previously selected for the purpose, or for that matter, if preferred, by the rather barbarous act of excising and examining a fragment of the muscle of a living one) may be freed of its parasitic guests; and it also shows how all risk of propagating tapeworm (without incurring the careful process of raising dead flesh up to a certain temperature) may be effectually prevented. The stockowner has but to remove his animals for six or eight months to localities where no fresh infection can occur, when at the expiration of the time mentioned all those cysticeri that did exist in the beasts at the time of the transfer will have perished. The flesh of the animals may then be eaten with impunity, whether well cooked or raw. This is an important teaching deducible from experimental inquiry, and we are rather surprised that it has hitherto escaped the notice of persons who, though they affect to ignore the value of scientific researches, are particularly anxious to parade their practical knowledge which, unhappily, too often proves a mere cloak for ignorance.

In conclusion, we have only sufficient space left to revert once more to the *brochure* by Giacomini. It affords many interesting details respecting a case in which there was a most unusual degree of infection of the human body by cysticeri. Dr. Giacomini institutes a searching comparison between the human measles procured by himself, and those of the pig sent to him by Professor Perroncito (*loc. cit.*, p. 10). In the human cysticeri he noticed a greater adherence of the capsule to the enclosed measles, and also observed that while the human measles-heads always displayed 32, or in some few cases 34 hooks, in two differently sized circles of 15 or 16 each, the

pig-measles, on the other hand, carried only 24 hooks to the double circle of equal circumference; consequently the hooks appeared to be more crowded together in the human parasite. This fact, as Giacomini remarks, does not of itself constitute an essential specific difference, since variations of the kind not unfrequently occur in cysticeri occupying one and the same host or bearer.

ANATOMY AND PHYSIOLOGY.

ARLOING ON THE PHENOMENA OF DEGLUTITION, AS STUDIED BY THE GRAPHIC METHOD.—In a communication to the Paris Academy on this subject (*Comptes Rendus*, November 2), the author points out the advantages of the method, and gives some of his results with it.

First, as regards the *respiratory apparatus*: the relations between respiration and deglutition have not been much studied, but they are remarkable.

Isolated Deglutition.—By this is meant swallowing of solid food at meals, or of saliva during abstinence. When tracheotomy has been performed on a horse (says M. Arloing), a noise is heard at each deglutition, denoting a sudden and considerable diminution of the pressure in the tracheo-bronchial system. The noise arises from introduction of the external air through the orifice made in the windpipe. This may be proved if a trocar be inserted in the latter, and the cannula connected with a capsule and recording lever. At the moment of swallowing, the lever suddenly goes down, and rises again, generally above its starting-point. This fall is produced almost constantly towards the end of the inspiration. The diminution of tracheo-bronchial pressure might be attributed to two causes; to dilatation of the upper part of the trachea, at the moment of ascent of the larynx, or to the raising of some part of the thoracic walls. The first cause must be put aside. It is true that if the ascent of the larynx be registered, it is found to coincide with the fall of the tracheal pressure; but this fall of pressure diminishes from below upwards. Further, if the upper part of the trachea be isolated, so as to be in connection only with the pharynx, the pressure is found to increase in it, while it diminishes on the chest side. We must, therefore, adopt the second hypothesis. It remains to determine if the dilatation of the chest is due to the ribs or to the diaphragm. If we register simultaneously the tracheal pressure, the movements of the thorax, and those of the abdomen, we find that the fall of pressure coincides with a very slight lowering of the ribs, and a well-marked rise of the abdominal viscera. These phenomena can only be explained by supposing a sudden contraction of the diaphragm at the moment when the larynx rises, and the pharynx, contracting, forces into the trachea a portion of the air it contains.

Successive Deglutition.—By this expression is meant the deglutition of drinks, done by successive draughts. During deglutition, the respiration is not suspended. A pneumographic cincture, placed on the thorax or the abdomen, as also a tube inserted in the trachea, continue to give curves, which, however, present differences, in that they diminish in amplitude, thereafter rising and exceeding their habitual dimensions, and their 'bristly' appearance indicates a series of very small complete respiratory movements, separated by shocks (*soubresauts*).

The shocks correspond to closure of the glottis and to the passage of the wave; and the small respiratory movements to the opening of the glottis, or to the short instant comprised between the passage of two waves. When the individual drinks with great avidity, the thoraco-abdominal walls are simply thrown into vibrations by the small respirations; and when the drinking ceases, the larger movements are resumed with unwonted amplitude.

Secondly, as to the *pharynx*: M. Arloing studied the modifications of pressure in the nasal cavities in man and the lower animals, and in the pharynx and commencement of the œsophagus in the lower animals only. In the case of man, he applied to the face a nose of lead, the cavity of which communicated with a registering apparatus; in the other case, a fine metallic tube was inserted in the nasal bone. Elastic capsules were introduced through the glottis, or into the œsophagus.

Isolated Deglutition.—By such processes it was ascertained that, at the moment of deglutition, there are (1), a forcing back of the air into the nasal cavities, then sudden aspiration; (2) contraction of the pharynx, then relaxation; (3) dilatation, and then constriction, of the œsophagus. In tracings taken simultaneously, it is perceived that there is synchronism, on the one hand, between ascent of the larynx, constriction of the pharynx, forcing back of the air into the nasal cavities and the top of the trachea, and dilatation of the commencement of the œsophagus; on the other hand, between descent of the larynx, aspiration of the air in the nasal cavities (sometimes also at the head of the trachea), the end of the constriction of the pharynx, and the beginning of constriction of the œsophagus. It is hence inferred—1, that, at the beginning of the second stage, there is a separation of the pharyngeal cavity (closed in front by the tongue applied to the palate) into two parts; that in the upper part the pressure increases, while it decreases immediately behind the lower part; and that it is thus necessary to suppose the elevation and tension of the velum of the palate, with Bérard, Debrou, and Maissiat; as also the dilatation of the origin of the œsophagus, with Haller, Maissiat, and Guinier; 2. That the dilatation of the origin of the œsophagus is due to the ascent of the larynx, to the traction which the muscles of the pharynx exert, from below upwards, on the fibrous cord which forms the lower limit of the latter, and, perhaps to traction exerted by descent of the diaphragm; 3. That the aspiration observed at the entrance of the nasal cavities has no connection with the dilatation of the œsophagus, seeing that it is manifested after this, when the pharynx falls back, and its cavity, resuming its ordinary dimensions, exerts a suction on all the neighbouring cavities.

Successive Deglutition.—It has been said that the deglutition of drinks takes place in the same way as that of solids; but differences have already been pointed out, and the following, in addition, occur in the pharyngeal cavities.

1. Man can drink with avidity and without noise, or without emitting a very marked noise. In the former case, the pressure remains uniform in the nasal cavities. In the latter the pressure undergoes changes, as in the deglutition of solids; this is the case also when one drinks with a pipette, either from a small glass, or from one in great part empty. These facts prove, that in the swallowing of drinks 'at a single draught,' (as is commonly said), the

velum of the palate is fixed after being raised, and that the changes of pressure which occur under it are not sensible above it. The respiration is thus suspended, or done by the mouth. In the horse, the velum of the palate is displaced at each deglutition, and the respiration is done by the nose.

2. Further, it appears that the *minima* rise in the curves of the pharynx, while they sink in the curves of the entrance of the œsophagus. The pharynx is thus subject to a mean and permanent constriction, which increases at each deglutition, while the initial part of the œsophagus dilates more and more, presenting, on the arrival of each wave, a new deglutition, which is added to the permanent dilatation, and immediately afterwards, a constriction which forces the wave into the tube.

There are thus well-marked differences between the deglutition of drinks and that of solids.

RIEDEL ON THE REGULATION OF ANIMAL HEAT BY RESPIRATION.—Franz Riegel communicates to *Virchow's Archiv* (Band lxi. Heft 3) a series of interesting observations on the temperature of animals, breathing by means of artificial respiration, through a cannula after tracheotomy, whilst under the influence of curara (woorara). As this substance tends to raise the temperature, and the number of respirations was quite under control of the operator, the experiments seem so far free from fallacy. They were suggested by Ackermann's fine work on the regulation of temperature in the higher animals (*Deutsches Archiv für Klinische Medicin*, Band ii. p. 361). Ackermann has striven to prove that a regulating mechanism for the temperature of the body is to be found not only in the skin, but in the organs of respiration; and he shows that, if the surface of a dog's body be exposed to an atmosphere of equal temperature to his own, or to a higher one, the frequency of his respirations rises in proportion to his temperature, even rising to 150 respirations per minute; and that this frequency of breathing is not due to deficiency of oxygen or excess of carbonic acid in the blood, but to the elevation of temperature. A form of dyspnoea exists, due simply to heat. Fick and Goldstein confirmed this (Ueber Wärmedyspnoea, *Inaugural Abhandlung, Würzburger Verhandl.* 1871).

Riegel observed long ago, that whilst simple warming of the animal greatly increased the frequency of his respirations, once even to 200 per minute, division of the spinal cord in the neck affected these but slightly. His present experiments (on rabbits and dogs) were designed to obviate some sources of fallacy in former ones. He has shown that, when the cervical spinal cord is divided high up, the increased frequency of respiration is no longer found, although the temperature of the surrounding air is raised. Hence the fact that such animals grow warmer in air of higher temperature than those whose cord is uninjured, does not justify us in concluding that division of the spinal cord elevates the temperature, or that there is an inhibitory centre there for heat, which is paralysed by the division of the cord. His experiments tend to show that respiration is an important regulator of heat, just as the skin is. They were carried out last winter in the pathological laboratory at Würzburg. The animals first had the windpipe opened, and a tube was introduced. Then curara was injected into a vein, in sufficient quantity to stop respiration, and produce perfect muscular relaxation. The degree of

curara-poisoning is important ; it must be sufficient to stop voluntary breathing, and keep down muscular action, but further degrees would be injurious. To obviate objections as to temperatures taken solely in the rectum, most of these animals had a thermometer simultaneously introduced through the jugular into the vena cava inferior [sic.—*Trans.*], and care was taken that the bulb of the thermometer should be freely movable in the vessel. The tracheal cannula was connected with an apparatus for artificial respiration, and the animal brought into a chamber with glass windows, provided with thermometers, and warmed by gas underneath. The air introduced was at the temperature of the air of the room (outside the apparatus in which the animal was placed). The number of cubic inches of air introduced each time were always the same—only the number of artificial respirations was altered.

The experiments, of which several are detailed at length, show that with all the circumstances remaining the same, except respiration, the temperature invariably sank, in proportion as respiration was quickened. Riegel has made experiments of similar nature, carrying on the artificial respiration through the nose, instead of doing tracheotomy. The results were similar, although less striking. He expressly disclaims the idea that we shall find an exact parallel in human beings, in whom he thinks the skin, differing from that of dogs or rabbits, plays a more important part in the regulation of heat. He does, however, claim for breathing an important share in the regulation of animal heat, even in ourselves. [The reporter thinks that many facts in pathology tend to strengthen this position. Dr. Edward Smith's experiments, confirmed now by many others both here and abroad, show that, with increased rapidity of respiration, there is diminished excretion of carbonic acid, and hence probably diminished chemical work—one of the chief sources of heat. It does not appear, however, that there was any regular correspondence or parallelism in Riegel's experiments, between the increased number of respirations and the diminished heat. In nature, when the number of inspirations is increased, the number of cubic inches of air changed each time does not generally, if ever, remain the same, but is diminished ; thus widely differing from one of the conditions of Riegel's experiments. These interesting experiments agree with the phenomena of hibernation, and with what is observed in the sleep of young children and young animals—slowness of respiration, with maintenance of equal heat in cold atmosphere, being most marked where epithelial appendages (fur, hair, and feathers) are most developed—for reasons which are obvious.] W. BATHURST WOODMAN, M.D.

CROMBIE ON THE DAILY RANGE OF NORMAL TEMPERATURE IN INDIA.—Dr. Crombie (*Indian Annals of Medical Science*, no. xxxii.) arrives at the following conclusions from numerous observations. 1. The temperature may be ascertained in the axilla for all practical purposes in ten minutes. The mean error after this time is only 0.153° Fahr. 2. The more recent observations of normal temperature in England show that the mean temperature of health in temperate climates has hitherto been overestimated, and that, instead of being put down at 98.4° or 98.6° , as in our text-books, it does not exceed 98° Fahr. 3. One of the effects of residence in the climate of lower Bengal on the health of Europeans is to raise their temperature from 98° to

98.5° Fahr. 4. Change of climate does not influence the character or extent of the daily fluctuation of temperature in health, which observes a curve running parallel with that of European observers, but half a degree higher, and amounts in India, as in England, to about 1.3° Fahr., ranging in the former from 97.7° in the early morning to about 99.0° in the evening, which are the periods of minimum and maximum temperature respectively in both countries. 5. Under all circumstances, not exceeding strictly physiological limits and including gentle exercise, a variation of nearly 2° Fahr. must be allowed for at every hour of the day, and an amplitude of fluctuation of body temperature of 2.6° Fahr., viz., from 97.3° to 99.9° Fahr. in the course of the twenty-four hours. 6. The chief causes of these variations from the usual curve are (1) exercise and food, which raise the temperature, and (2) sleep at unusual hours, which depresses the body temperature. Excluding these causes of deviation, the variations of temperature at each hour of the day are limited to 1° Fahr., that is to say, to half a degree on each side of the normal daily curve of temperature of Europeans in India. 7. The effect of exercise in raising the temperature of the body is invariable and generally considerable, and occurs at all periods of the day ; even after such gentle exertion as that of dressing or changing from the recumbent to the sitting posture, a rise of temperature is observed. The effect of food is less marked, but is distinct after the morning and midday meals. It is lost in the downward tendency of the normal curve of daily fluctuation which takes place at the time of the evening meal. The diminution of temperature during sleep is considerable at all times. 8. The temperature of the body is raised by whatever hinders radiation and evaporation from the surface as a warm atmosphere or thick badly conducting clothing. It is lowered by whatever promotes radiation and evaporation from the surface, as light clothing, the use of a punkah, or a prolonged cold bath. 9. The temperature of natives in India, including East Indians, is higher than that of Europeans resident in it by about half a degree Fahr. 10. The temperature of children is lower than that of adults during the first week after birth. Immediately after birth a very rapid and great diminution of temperature occurs, especially in feeble infants, amounting to 4° or 6° Fahr. in half an hour. This depends on exposure (radiation and evaporation) and the inability of the calorific function suddenly called into force to compensate for the sudden removal of the external (maternal) sources of warmth which occurs at the moment of birth. The temperature of children is liable to greater variations than that of adults from similar causes acting on them afterwards. The health of an European in India may be regarded with suspicion if his temperature is persistently above 98.5° Fahr. in the early morning, or 99.5° Fahr. in the evening, and is not due to exercise. A temperature of 99.0° Fahr. in the morning, or 100° Fahr. in the evening at rest is not incompatible with perfect health in the case of natives. 12. These remarks refer to temperatures taken in the mouth. A deduction of 0.25° should be made from these figures in estimating the value of an observation made in the axilla, or 0.4° should be added if the temperature is taken in the rectum,

T. LAUDER BRUNTON, M.D.

MEDICINE.

HELLER AND THURN ON TRANSFUSION OF BLOOD.—In the *Berliner Klinische Wochenschrift*, August 10, Staff-Surgeon Dr. Heller, of Danzig, relates the case of a soldier, aged twenty-four and a half years, who had ulcers of the stomach, with hæmatemesis and bloody stools. Many remedies were used, including the subcutaneous injection of ergotine; but nothing arrested the bleeding, and the patient was becoming exhausted. On November 27, 1873, at 1.30 P.M., transfusion was performed according to Hasse's method; 360 grammes ($12\frac{3}{4}$ ounces) of sheep's blood being injected. The temperature before the operation was nearly normal. At 2 P.M. it was 101.1° Fahr.; at 2.30 P.M. 103.6° , and afterwards rose to 107.6° . The countenance remained pale, but the pulse became fuller and stronger. He had previously been unable to move himself in bed; but was now able to move on to his right side. Severe rigors came on at 4 P.M., and lasted until 5.30. He then dozed for an hour and a half, often waking to ask for a drink of water. The pulse and respiration were much disturbed. He threw himself about, and loosened the bandage on the arm, which caused some bleeding. Suddenly, about five hours after the operation, he died. The temperature a quarter of an hour before death was 105.26° Fahr. At the *post mortem* examination, pyloric disease and ulcers were found in the stomach, which was also nearly filled with blood. In commenting on this case, Dr. Heller says that at first he regretted that he had not used lamb's blood; and he also feared that too much blood had been injected and too rapidly, as was apparently shown by the rapid rise in the pulse and temperature, and the fresh hæmorrhage into the stomach, but on reading Gesellius' cases he came to the conclusion that these surmises were ill-founded.

The same journal contains a paper on the direct transfusion of lamb's blood, by Dr. Thurn, of Niederrad, near Frankfurt. Several cases are given. H. O., aged thirty-six, was supposed to be consumptive, with night-sweats, cough, diarrhoea, and extreme weakness. For a long time he had been subjected to various kinds of treatment without relief. On March 20, 1874, at 3.30 P.M., assisted by Dr. Stahl, assistant-physician to the Frankfurt Hospital, transfusion was begun. The temperature was 98.24° Fahr., the pulse 88. For the first thirty-five seconds no symptoms appeared. After forty seconds the veins filled, and he got more colour. At fifty seconds he began to breathe quickly, and this increased up to ninety seconds, when he laboured for breath, and the sight was confused. At the end of 105 seconds he seemed to be fainting, and the transfusion was stopped. The temperature was 98.9° Fahr., the pulse 92. The difficulty of breathing lasted fifteen minutes, and then gradually diminished. He complained of great heat and pains in the back. At 4.15 P.M. a severe rigor came on which lasted an hour. The temperature was 103° Fahr.; the pulse 116; pains in the back and head, and heat of body continued to 8.30 P.M., when he perspired; at 9 P.M. the temperature was 99.14° Fahr. * On March 21, he had had a good night. The morning temperature was 98.4° Fahr., the pulse 84. He felt somewhat improved, and had a better colour. At 9 A.M. he passed some urine which contained albumen and blood-corpuscles. This continued throughout the

day. The evening temperature was 100.2° Fahr., the pulse 96. On March 22, the temperature in the morning was 98.8° , in the evening 100.6° Fahr. He was able to leave his bed, which he had not done before for some time. There was albumen, but no blood in the urine. On March 24, he was able to go out. The albuminuria was less. On April 2 he was improved in every respect. He had had a little urticaria; the urine was normal. The instrument used was an India-rubber tube, with a glass tubule at each extremity. The lamb was between five and six weeks old, and lost during the operation 530 grammes (nearly 19 ounces) of blood, about half of which was transfused.

Dr. Thurn has had four other cases. Three were cases of phthisis. Hasse's method was used in all. In one case neither blood nor albumen was observed in the urine. Two of the patients decidedly improved; another was in the last stage of consumption, and died four weeks after the operation, after having felt better for the first fourteen days. The quantity of blood used was from 180 to 200 grammes. The fourth was a case of severe menorrhagia. The patient became bloodless, unconscious, and was apparently dying. Subcutaneous injections of ergotine and cold applications were used without avail. Transfusion was performed on May 5, 1874, at 11.30 A.M., and lasted 125 seconds; pulse, 120; respirations, 36. The patient became conscious during the operation and complained of pain in the back and oppression of breath. The lamb had lost 390 grammes in weight. At 12 o'clock there was great heat of skin and pain in stomach. At 1.30 P.M., she had rigors, lasting nearly an hour; temperature, 101.3° Fahr.; pulse, 96. After the rigor she slept for an hour and a half, and felt better. The menorrhagia was much less; cold applications were continued. Next day she felt improved, but very weak, with occasional pains in the back. In the morning the urine contained blood; in the evening this had disappeared and had given place to albumen. In a few days the albumen also disappeared, and in six days the patient was placed on tonics, and ultimately recovered.

[Whatever may be said of transfusion as a therapeutic agent, these cases are of interest regarded simply as physiological experiments. The occurrence of hæmaturia and rigors after transfusion with lamb's blood seems to be the rule, and these are certainly unfavourable features in the proceeding. I do not remember any mention of similar symptoms following transfusion with human blood. The explanation given of the hæmaturia is, that the serum of the blood of one animal dissolves the blood-corpuscles of another of a different species, and is then excreted by the kidneys.—*Ref.*]

HENRY M. MADGE, M.D

MATTERSTOCK ON THE CHOLERA VOICE.—Dr. G. K. Matterstock gives an interesting report (*Berliner Klinische Wochenschrift*, no. 39, 1874) on the laryngoscopic aspects of the cholera epidemic in Würzburg, in the months of July, August, and September, 1873.

Out of fifty-one severe cases (children included) twenty-two were completely aphonic; in twenty-one there was more or less hoarse voice; in five there was no alteration of the voice; and three patients, owing to the advanced asphyxia, were no longer in a condition to attempt to speak. The character of the epidemic was throughout of the transudative

form. With regard to the relation of the cholera voice to the other symptoms, especially in relation to transudation, it was remarked that the quantity of the fluid evacuated *per os* and *per anum* had no material influence on the earlier or later commencement of changes in the voice, nor on the amount of those changes. The presence of the cholera voice was—in accordance with the observations of Krombholz, Stäger, Tosi, Serafino, and others—a most unfavourable prognostic sign. The patients with aphonia were the severest cases, and all died.

The *vox cholericæ* has hitherto been attributed by some (Merkel, Schultz, etc.) to the drying of the mucous membrane of the larynx and of the laryngeal muscles, from the transudative process; others (Levy, Stäger, etc.) regard it as a purely nervous symptom. The repeatedly observed facts, that the cholera voice bears no proportional relation to the transudation; that patients with profuse watery evacuations were neither earlier nor more completely aphonic than those with less copious secretions; that, on the other hand, in many epidemics, the aphonia was one of the first signs of the cholera process, and occurred before the patient had suffered much from transudation; that epidemics have been described, in which there was no change in the voice (in spite of the severity of the other symptoms); that the highest degree of aphonia occurred precisely in those '*foudroyantes*' cases, where the transudation was slight—all these facts yield abundant evidence against the drying-up theory. There is greater probability in favour of the neurotic doctrine. The absence of any evident anatomical changes in the larynx, and the presence of many other symptoms (such as the paralysis of the skin and vascular system, the condition of the pupil, the arrest of secretion, the præcordial oppression, the hebetude in the severe cases, the lowered tone, and cramp of the muscles, the more or less impaired reflex action, etc.), which can best be explained through the nervous system, render it probable that the alterations in the voice of cholera patients are of a paralytic character. The following facts support this doctrine. Fifteen patients were examined laryngoscopically. All were severe cases; most of them had copious rice-water evacuations, pulselessness, cyanosis, and coldness, cramps, anuria, etc.; nine patients were completely aphonic at the time of the examination, four were hoarse, and two were no longer in a condition to speak, owing to their extremely apathetic condition. The examination was made with ease in all the cases (except in those of the two patients just referred to), there being complete absence of the reflex acts, such as swallowing, choking, and coughing. The lining membrane of the larynx was cyanotic, like the mucous membrane of the lips and mouth; the vocal cords had a dirty appearance, and were slightly injected. The laryngeal mucous membrane gave the impression of dryness from its shining appearance. As regards the form of the glottis, the prominence of the vocal processes was the most marked feature; the vocal cords appeared elongated, and the border of the membranous glottis had a strongly sickle-like excavation directed outwards. The same position of the vocal processes was also seen on *post mortem* examination (when the configuration of the glottis was observed without opening the larynx). On laryngoscopic examination, the vocal cords were seen to present different appearances, both during quiet respiration and on attempted phonation.

In quiet respiration two forms were observed: In one form (presented by two patients) the glottis was widely open, and the vocal cords showed a proper respiratory action; in these cases the sickle-shaped excavations of the membranous glottis and the knee-like projection of the vocal processes, were very marked. The second form was observed in the remaining cases; in these the glottis presented a more or less cadaveric position; the vocal processes approached each other, and divided the glottis into an anterior elliptical space and a posterior one, which varied in shape according to the degree of approximation of the arytenoid cartilages. In these cases the respiratory action of the vocal cords failed altogether, or was only slightly perceptible on deep inspiration; in a few cases in forced respiration, there was an unusual trembling of the vocal cords.

On attempted phonation, the form of the glottis showed either a diminished or an increased approximation of the vocal cords. In seven cases, all of which were aphonic, there was no movement of the vocal cords. These cases all belonged to that form, in which there was also an absence of respiratory movement. In the remaining cases there was a certain amount of respiratory action of the glottis. In two of the aphonic patients the vocal processes almost touched, but the vocal cords were otherwise separated along their whole extent, and in two cases, in which there was hoarseness, the vocal processes were in contact, and the vocal cords were scarcely separated at all, and there was juxtaposition of the cartilages of Santorini; finally, in two cases, where there was a hoarse voice, the arytenoid cartilages advanced well to the median line; the cartilaginous glottis closed completely, and the vocal processes approximated, but the membranous glottis remained open, and presented a canoe-shaped form. In some cases the paralytic signs were more marked on one (always the left) side.

Taking into consideration both the laryngoscopic signs, and the symptoms bearing on the disturbance of voice in the first seven cases, there was a cadaveric position of the glottis in respiration and phonation, immobility or diminished action of the vocal cords and arytenoid cartilages, sickle-shaped excavation and trembling movement of the vocal cords, complete aphonia, the peculiar breathlessness which affected all the severe cases both in speaking and coughing—a combination of symptoms which, the author believes, point to a general paralysis of the laryngeal muscles. The remaining cases showed, with a varying degree of voice-change, a special implication of certain groups of muscles; and, in the form last referred to, the action of the tensors and adductors of the vocal chords was particularly affected. The abductors must also have been implicated in certain cases, viz. those in which the knee-like projection of the vocal processes was present, and the outward movement of the vocal cords impaired. Not only did the laryngoscopic appearances and the other symptoms point to a disturbance of innervation of the muscular apparatus of the larynx as the cause of the cholera voice, but the psychological phenomena of the aphonia, and certain therapeutical experiments led to the same conclusions. Thus the sudden, but temporary return of voice, under emotional conditions, common in ordinary nervous aphonia, was observed in the case of several of the cholera patients.

Oliver's method of laryngeal gymnastics (in which

compression is applied to the wings of the thyroid cartilages, at the same time that attempts are made at phonation) was applied to many of the cases, and all the patients, on whom the method was tried, recovered a more or less hoarse, but still resonant, voice, which lasted a shorter or longer time. A similar result followed the application of a rather strong induced electric current to the skin, the electric contractility being perfect in all cases in which it was tested.

MORELL MACKENZIE, M.D.

BEARDSLEY ON MALARIAL PARAPLEGIA. — In *The Clinic*, October 3, 1874, Dr. C. E. Beardsley reports four cases of paraplegia in children from three to five years of age, who were seen twenty-four hours after the first attack. All of them were females, healthy in appearance, well nourished and well clothed. None complained of pain. The temperature was nearly normal. The pulse was regular, but a little accelerated. They were cheerful, with good appetite. There was no difficulty in micturition or defæcation. The muscles of the upper extremities were perfect in all of their movements and obeyed the dictates of the will. There was anæsthesia of both lower extremities, with absolute paralysis of all the muscles. The above symptoms were developed suddenly without any known cause, but were accompanied by a piercing cry and loss of motion. One of the cases proved fatal. Spinal congestion probably existed in all of them, and in two spinal hæmorrhage occurred, malaria being the cause in all. The treatment consisted of first a saline purgative, followed by bromide of potassium for some hours with quinia; then quinia alone some hours; finally the galvano-faradic current.

OBSTETRICS AND GYNÆCOLOGY.

STRONG AND STEELE ON THE DETERMINING OF THE SEX IN UTERO.—Drs. Albert B. Strong and D. A. K. Steele reported to the Chicago Medical

Society (*Medical Examiner*, August 15, 1874) the following observations deduced from the examination of one hundred cases.

1. In the majority of cases, male foetal hearts are slower than female. 2. One hundred and thirty-two foetal pulsations per minute is the average which constitutes a dividing line between the sexes. Below this, sixty-eight and four-sevenths per cent. are males, twenty per cent. are females, eleven and three-sevenths per cent. are doubtful. Above this fifty-three and one-third per cent. are females, twenty-six and two-thirds per cent. are males, twenty per cent. doubtful. 3. The most accurate observations are made during the last four weeks of gestation. 4. The rapidity of the heart's action is increased in proportion to the feebleness of the foetus. 5. Calcareous or fatty degeneration of the placenta renders the pulsations feeble and irregular. 6. In some cases it would be possible to diagnose diseased conditions of the placenta by careful observation of the foetal heart.

Of fifty cases examined consecutively, twenty-seven gave birth to female children and twenty-three to males. The lowest rate observed was 118; it occurred but twice; one each in a male and female child. The highest rate noted was 180, occurring three times, twice in males and once in the case of a female. The average rate of the male pulse was 136.3; of the female, 137; of both sexes, 136.7. Considering the latter as the dividing line between both sexes, a pulse at and below this rate may be referred to males, and that above it to females. In twenty-six cases the sex was correctly predicted, and in twenty-four an error was made.

If the cases be excluded where there was unusual activity of the foetus, the average rate of the male pulse will be found to be 133.6; of the female, 136.2; of both sexes, 134.7.

Considering, then, 134 as the dividing line between the sexes, the diagnosis was correct in twenty-four cases and incorrect in twenty-two. If, however, 128 be taken as the dividing line, the diagnosis was correct in twenty-eight cases and incorrect in twenty-two. There were six female children whose pulse was steady below 128; five males had a steady pulse between 128 and 138; three, between 138 and 148; two, between 148 and 158; and one between 158 and 168. So far as the facts elicited from these observations are of value, it is evident that they have utterly failed to furnish a basis for determining the sex *in utero*.

The observations were conducted by the aid of an ordinary Camman's stethoscope, and our experience has made it clear that more distinct sounds are audible when the bell of the instrument is moistened and applied to the abdomen without pressure, as the peculiar thrill of the foetal heart is lost when the stethoscope is grasped by the fingers.

In conclusion, an opinion as to the sex of the child, founded on the rate of the foetal pulse, is of little more value than a guess; while the presentation generally, and the exact position possibly, may be accurately determined.

JACOBS ON A SUCCESSFUL CASE OF CÆSAREAN SECTION, BOTH AS REGARDS MOTHER AND CHILD. Dr. Jacobs, of Cologne (*Berliner Klinische Wochenschrift*), October 19, 1874, reports that a woman, forty-two years old, a multipara, was delivered two years before with difficulty by the forceps. The conjugate diameter was barely two inches; the

horizontal rami of the os pubis were so driven inwards that the symphysis pubis projected like a beak. A careful examination showed that she was suffering from osteomalacia of the pelvis. As the child was living, it was, after consultation, decided to perform Cæsarean section. The patient was placed under chloroform, and the abdomen was rapidly divided through the linea alba, care being taken to empty both bladder and rectum previously. The incision into the uterus struck upon the placenta, which was detached as far as was requisite to remove the foetus. The placenta was removed immediately after the delivery of the foetus, without any difficulty. The uterus was then compressed and squeezed downwards. No sutures were placed in the uterus, only in the abdominal walls, which were brought together in the usual manner. There was some sickness from the chloroform, which was arrested by the internal and external administration of ice and ice-water. Only a portion of the abdominal wound healed by first intention; the rest granulated. Dr. Jacob considers that the successful result was mainly due to the rapidity with which the operation was performed, and the application of ice.

[This is the third successful case that has been reported lately; two were by pupils of M. Depaul, who strongly advocates the immediate removal of the placenta and the non-use of sutures to the uterus. He also recommends the insertion of a long seton through the two wounds, and out through the vagina. This method was adopted in each of the cases of his pupils.—*Rep.*] W. C. GRIGG, M.D.

PSYCHOLOGY.

PARRISH ON THE PATHOLOGY OF INEBRIETY.—Alcoholism, according to Dr. Joseph Parrish, must be looked upon as a secondary condition dependent on the real disorder which he proposes to discuss. In studying the symptoms and conditions which constitute alcoholism, we do not reach its causes and pathology. What is the diathesis, the constitutional tendency, or condition, which leads to the excessive use of alcoholic liquors? He believes the diseased condition to be one chiefly of alimentation. Our appetites vary as to articles of diet; the eating of lime, chalk, clay, etc., shows a disordered alimentation amenable to correction. We are familiar with the demands of appetite or longing in pregnancy, and in convalescence from fever; and the excessive demand for alcoholic stimulants may be placed in the same category. This morbid condition may be the result of disease, or we may recognise in it a pre-natal diathetic condition, which may be developed in the years of minority, or after threescore years of

sobriety. Observation has led the writer to believe that in many cases the solar plexus is the seat of the disease of inebriety. As in some inebriates mental symptoms predominate, so in others the head is less disturbed, and the gastric region is the seat of suffering. He is not satisfied as to the asserted relation between insanity and intemperance. Sometimes inebriety is the exciting cause of insanity, but the facts are over stated. It is his observation that intemperance sometimes takes the place of insanity; that is to say, a person who is in danger of insanity from excessive mental strain or shock, may resort to the bottle and become oblivious of his troubles by a drunken bout, during which the insane tendency explodes or exhausts itself, and the patient recovers. Dr. Parrish discusses the question of treatment, and says that we must deal with inebriety in public and private as a disease, and that restrictive legislation should be applied to the consumer chiefly. The remote or constitutional causes of insanity cannot be directly reached by law, nor can its proximate causes be controlled, except so far as the individual is concerned, under the operation of his own intelligence [and a co-operative public sentiment; and the same may be said of inebriety. The law cannot penetrate the occult forces of our being; it cannot purify the source of disease or divert its current. The real source of prevention is an appreciation by the people of what intemperance really is—a condition of disease that should come as much under the care of the family physician as any other malady. The medical prescription to the inebriate would be uniform and positive, that entire abstinence from intoxicants of all kinds should be the rule of his life, together with the observance of such dietetic regulations as may not offend his sensitive nerve-structure, and the use of such remedies as will promote its renovation, and, if possible, prevent the recurrence of old desires. It is not the appetite for liquor alone, but all the undue cravings of a disordered gastric system, that are to be regulated. It is the general rather than the special condition that is to be treated, and the inebriate should put himself in harmony with the elevating agencies of social and religious life, so that his impaired and enfeebled will may be strengthened, not for the purpose of destroying his natural propensities, but of controlling and regulating them.

MACLAREN ON GENERAL PARALYSIS OF THE INSANE.—Mr. James MacLaren reports (*Edinburgh Medical Journal*, October, 1874), an interesting case of prolonged general paralysis of the insane. He quotes authorities to show that it is rare to find a case of this disorder lasting more than a few years. The patient in question was admitted into the Royal Edinburgh Asylum in May, 1860, as a case of general paralysis, the symptoms being inequality of the pupils, unsteadiness of gait, and indistinctness of speech. The mental characteristics were chiefly considerable melancholia with stupor. He continued unchanged for a year, and was then, for some reason not stated, discharged 'not improved.' In January, 1863, he was re-admitted. He was then silent and stupid, with the indications of paralysis above mentioned. In three months he took to walking round the grounds, and said he was quite well and happy, but articulated with the greatest difficulty. In another three months he commenced to exhibit the characteristic delusions of grandeur. He had the most glorious ideas of his riches, strength, might,

beauty, etc., was forty feet high, was God, was married to the Queen, was the strongest man in the world, and had a 'damnable heap o' money.' In another three months he was more subdued in mind, and weak in body; a little afterwards, he had a series of epileptiform seizures, which were ushered in by a regular congestive attack. He became very weak, and could hardly swallow or speak. Two months later, he was walking about as usual. In March, 1864, the entry was 'no change: is a magnificent specimen of a general paralytic.' On December 15, of the same year, he is noticed as generally failing, and in the March following was too frail to be up. He then rallied, and improved so much during the next three years, that he was tried in the lunatic wards of the Leith poorhouse. He became violent and dangerous, and was returned to the asylum. At present he is staggering and uncertain in his walk, and much down on the left side. The pupils are unequal, the left being the larger. He articulates with difficulty, and with the peculiar stutter of the general paralytic. His tongue is tremulous when protruded. He is dirty in habits and obscene in conversation; full of delusions as to his importance, facile and vacuous. He is a great thief, and hoards up all manner of rubbish, which he thinks of great value, and will decorate himself with tawdry finery. Such a case is remarkable, and the remissions might lead the uninitiated to believe that there is such a thing as recovery from the disease.

G. FIELDING BLANDFORD, M.D.

MAUDSLEY ON THE LEGAL TEST OF INSANITY.—Dr. Maudsley (in *Responsibility in Mental Disease*) has written a most useful chapter on the history of the endeavours which have been made in this and other countries to lay down a legal test of criminal responsibility in mental disease, which may be summed up as follows.

At first, two kinds of insanity only seem to have been recognised by English law—idiocy and lunacy. As time went on, Lord Hale recognised a partial insanity as distinct from total insanity. In 1723, Mr. Justice Tracy said: 'It is not every kind of frantic humour, or something unaccountable in a man's actions, that points him out to be such a madman as is exempted from punishment; it must be a man that is totally deprived of his understanding and memory, and doth not know what he is doing, no more than an infant, than a brute, or a wild beast; such a one is never the object of punishment.'

In 1800, at the trial of Hadfield for shooting at the King in Drury Lane Theatre, Mr. Erskine, counsel for the defence, argued that delusion was the true character of insanity.

In 1812, at the trial of Bellingham, for the murder of Mr. Spencer Perceval, the Attorney-General decided that, 'a man was answerable for his criminal acts if he possessed a mind capable of distinguishing right from wrong.'

In 1843, at the trial of McNaughten, for the murder of Mr. Drummond, the judges, in answer to the House of Lords, stated that, 'to establish a defence on the ground of insanity, it must be clearly proved that at the time of committing the act, the party accused was labouring under such a defect of reason from disease of the mind as not to know the nature and quality of the act he was doing, or, if he did know it, that he did not know he was doing wrong.'

More recently, in America, in the case of State v. Pike, Chief Justice Perley instructed the jury that they should return a verdict of not guilty, if the killing was the offspring of mental disease in the defendant. And the revised statutes of the State of New York enact that, no act done by a person in a state of insanity can be punished as an offence.

In France, the article of the penal code is: 'There can be no crime nor offence if the accused was in a state of madness at the time of the act.'

In Germany, the section of the penal code is: 'An act is not punishable when the person at the time of doing it was in a state of unconsciousness or of disease of mind, by which a free determination of the will was excluded.'

Dr. Maudsley concludes an able discussion of this most difficult question as follows:—

'It is abundantly evident from this short review of the codes of other countries, that nothing can be said in justification of the superstitious reverence with which English lawyers cling to their criterion of responsibility.'

H. SUTHERLAND, M.D.

DERMATOLOGY.

KAPOSI ON A SECOND ATTACK OF BILATERAL ZONA.—Dr. Kaposi (Moritz Kohn) publishes in the *Wiener Medizinische Wochenschrift*, no. 38, a case of recurrence of herpes zoster. The first eruption affected the left hand, arm, and shoulder, including the skin which covered the trapezius and the scapula, and also the anterior and lateral regions of the chest on the right side. This lasted from April 22 to May 1, and left behind it scars and maculae. Some of the former were large and painful, resembling cicatricial cheloid. On June 25, the same patient presented himself with a fresh eruption of zona. The vesicles occupied the back of the left forearm, and closely surrounded a long bleb and a large dark-green crust. The following day the eruption appeared on the left arm, above the elbow, and afterwards spread to the shoulder. One small patch showed signs of gangrene, but otherwise the disease ran a favourable course, and the crusts were drying up, when, on July 8, pain was felt in the right mammary region, followed by a second eruption of vesicles in the same place as in the first attack. This extended over the first, second, fourth, and fifth intercostal spaces in front, but soon subsided. There was no fresh eruption, but the pustules and ulcers of the left arm were painful and long in healing. [The only other case to which Dr. Kaposi can refer is one by Dr. Wyss, in vol. xii. of the *Archiv der Heilkunde*, p. 290. Here the zoster was lumbo-abdominal; the patient said he had suffered from the same disease in the same place thirty years before, and the scars which were still visible confirmed the statement. Bateman, however, says that herpes zoster may occur more than once in the same individual, and Dr. Tilbury Fox says (*Skin-Diseases*, p. 202), 'The disease rarely occurs twice in a lifetime, but I have known it occur a third time.' That zona may extend to both sides of the body without a fatal result has been known from Tulp's case (*Obs. Med.* lib. iii. cap. 44) in 1652, to those narrated by Bärensprung, Hebra, and Hardy.]

WOLFF ON SCLERODERMIA ADULTORUM.—Dr. J. Wolff brought the following case before the Medical Society of Berlin (*Berliner Klin. Wochen-*

schrift, September 21). The patient, twenty-two years old, found the left knee stiff early in last May. The skin of the ham became hard and inflexible, and in a few days he could not bend his knee. Within two months the affection had spread down the leg and half-way up the thigh. At the end of June the disease had reached its full extent. The skin was then hard, shining, and adherent, so that it could not be raised in folds, and the knee could not be fully extended. [The colour and surface of the skin appear not to have altered, and no mention is made of pain.] From that time, however, involution began, and when the report was made, a fortnight later, the skin on the front of the knee, and the lower third of the thigh, had recovered its normal condition.

[Dr. Wolff appears to be unacquainted with Dr. Fagge's paper on keloid and scleriosis in the *Guy's Hospital Reports* for 1867, in which several similar cases are recorded, of rapid course and rapid involution of scleroderma in adults.—*Rep.*]

WOLFF ON SCLERODERMIA MALIGNA.—At the same meeting of the Medical Society of Berlin, Dr. Wolff announced the result of the case of 'Scleroderma maligna,' reported in the LONDON MEDICAL RECORD, May, 1873 (vol. i. p. 299). The patient, a man aged fifty, was attacked by pain at the angle of the right jaw, in March, 1872. The skin became dense and hard, and the head was drawn down by its contraction. By the beginning of 1873 the induration had spread over the upper part of the chest, and the whole of the right half of the neck. There were no ulcers, no enlarged glands, and no signs of internal mischief; but, from the pain and the 'malignant' course of the disease Dr. Wolff regarded it as the form of cancer described by Velpeau as 'squirrhe en cuirasse,' when affecting the female breast. A piece cut out at this date showed bird-nest capsules and epithelial cells in the loculi of a network composed of white and yellow-elastic fibres.

The patient died (apparently early in the present year, but neither the date nor the preceding symptoms are stated), and the necropsy made by Professor Ponfick fully confirmed the above diagnosis. He described the integuments of the face, neck and chest as infiltrated with scirrhus, which had undergone fibroid contraction; and a recent nodule of cancer was also found in the thyroid.

P. H. PYE-SMITH, M.D.

MISCELLANY.

IN our notice of the late Dr. Edward Smith, in last week's MEDICAL RECORD, it should have been mentioned that among his latest works was one on *Foods*, published by Messrs. King & Co., in the International Scientific Series.

EXTIRPATION OF THE LARYNX.—Professor Billroth performed this operation for the second time on November 11, in the General Hospital of Vienna, on a man aged fifty, suffering from epithelioma of the larynx. The patient died at midnight on the 16th, apparently from hypostatic pneumonia.

STATISTICS OF DISEASE IN GERMANY.—The report of the commissioners on this subject recommends that public notice shall be given by medical practitioners of all cases of scarlet fever, diphtheria, petechial typhus, trichinosis, hydrophobia, and glanders, and that information of all cases of cholera and small-pox shall be given by the masters of the houses in which they occur.

PROFESSORS AND STUDENTS.—The medical schools of Paris and St. Petersburg have lately been the scenes of demonstration, on the parts of the medical students, against certain professors. In Paris, the school has been closed in consequence of the disorderly conduct of the students, when Professor Chauvaffard was about to deliver his introductory address. In St. Petersburg, the object of dislike is Professor Cyon, whom the students desire to have removed on account of the strictness with which he conducts examinations. It is said also that he has given no lectures for the last two months.

TOBACCO-POISONING.—Professor Chevallier reports in the *Journal de Chimie Médicale*, the case of a young man who laid a wager that he would smoke twelve cigars. He felt decidedly uncomfortable at the end of the eighth, and when he had finished the ninth, he was attacked by giddiness and shiverings. These symptoms became worse after the tenth cigar. He refused to leave off smoking, but went home in charge of some friends. He was there attacked by severe pain in the bowels and vomiting. A medical man was called in who could not, however, stop the progress of the attack, and the patient died in the night. It must, however, be taken into account that the victim was suffering from hypertrophy of the heart.

THE ROYAL SOCIETY.—The medals in the gift of the Royal Society for the present year have been awarded by the Council as follows, and will be presented at the anniversary meeting on the 30th inst.:—The Copley Medal to Professor Louis Pasteur, of the Academy of Science, Paris, for his researches on fermentation and on pebrine; the Rumford medal to Mr. J. Norman Lockyer, for his spectroscopic researches on the sun and on the chemical elements; a Royal Medal to Professor W. C. Williamson, of Owens College, Manchester, for his contributions to zoology and palæontology, and especially for his investigations into the structure of the fossil plants of the coal-measures; and a Royal Medal to Mr. H. C. Sorby, for his researches on slaty cleavage and on the minute structure of minerals and rocks, for the construction of the micro-spectroscope, and for his researches on colouring matters.

ANOINTING WITH COCOA-BUTTER IN SCARLET FEVER.—Upon the recommendation of Schneeman, the anointing of the body with fat has been extensively practised in Germany during more than twenty years, with the view of lowering the temperature, and hastening the desquamation. Dr. Bayles suggests, in this connection, the employment of cocoa-butter, as producing a more cooling and refreshing effect upon the patient, and emitting a more agreeable odour in the sick chamber. This agent, on account of its solid consistence, is more readily applied than either fat or oil, and is more easily absorbed by the skin. Furthermore it is thought to afford the system a certain amount of nourishment. In severe fevers, the entire surface of the body should be rubbed with this substance every hour, or at least once every four hours. Its application is also recommended in typhoid fever, in cases where the patients manifest a dread of water, or where the application of water is impossible; likewise in other inflammatory diseases, especially the severer forms of inflammatory rheumatism, and in tuberculosis.

STATISTICS OF INEBRIATE ASYLUMS.—In the New York State Inebriate Asylum, at Binghamton, from September 1, 1873, to September 1, 1874, the number of patients admitted was 190. Of these twenty-three, or thirteen and one-third per cent., have proved refractory and unresponsive. The rest have quietly submitted to the rules and disciplines of the institution; and many have gone out, as is believed, fully restored. Measures are now being taken to inquire into the subsequent history of all those who have been inmates of the institution. A small proportion relapse. Of the 190 inmates during 1873-4, one has returned three times, and sixteen are there for the second term of treatment. But there is a propen-

sity to return in many diseases, especially when the person is exposed to the exciting causes. Mental disorders, as is well known, are very liable to return; and the records of the lunatic asylums will probably show quite as many relapses in proportion as will the inebriate institutions.

SUICIDE AMONG THE ANCIENTS.—The following table of suicides of ancient Greeks and Romans compiled by Dr. O'Dea is of interest:

| NAME. | MODE. | CAUSE. |
|---------------------------------|--------------------------|--|
| Pythagoras | Starvation . . . | Tedium vitæ. |
| Demosthenes . . . | Starvation . . . | Downfall of Athens. |
| Clitomachus . . . | ? | Tedium vitæ. |
| Stilpo | Intoxication . . | ? |
| Metrocles | Suffocation . . . | Old age. |
| Menippus | Hanging | Financial losses. |
| Demomax | Starvation . . . | Loss of influence consequent on old age. |
| Zeno | Strangulation . . | Fracture of a finger. |
| Seneca | Phlebotomy . . . | Political reasons. |
| Pauline, wife of Seneca | Phlebotomy . . . | An attempt caused by unwillingness to survive her husband. |
| Cato | Wound | Political reasons. |
| Otho | Wound | Political reasons. |
| Panthea | Poison | Grief at the loss of her husband in battle. |
| Phila | Poison | Defeat and flight of her husband. |
| Arria | Wound | Defeat and arrest of her husband. |
| Scipio | Wound | Because he had fallen into the hands of his enemies. |
| Socrates | Starvation . . . | The victory of Philip at Chæroneæ. |
| C. Lutatius | Suffocation . . . | To avoid falling into the hands of Marius. |
| Lollius | Wound | The ill-will of Caius Cæsar. |
| Nero | Wound | Because condemned to death by the Roman Senate and people. |
| Lycambus | Hanging | Ridicule. |
| Lambianus | Self-interment . . | Because his writings were condemned and burned. |
| Aristarchus | ? | A dropsy. |
| Erasistratus | Poison | An ulcer. |
| Eratosthenes | ? | Loss of sight. |
| Sylvius Italicus . . . | Starvation . . . | An incurable disease. |
| Diogenes | ? | A violent fever. |
| Porcia | Swallowed live coals . . | Domestic affliction. |

AMERICAN DIPLOMAS.—The *Philadelphia Medical Times*, one of the ablest and most independent of medical journals has the following rather startling observations on this [subject, which occasionally interests our registering boards.—Encouraged by the old saw, 'A continual dropping will wear away a stone,' at the risk of wearying our readers we to-day call attention to the Indiana Medical College as an example of the inevitable results of our American system of medical instruction. In the recent announcement of this college it is stated, 'The Indiana Medical College was organised in 1869, to meet an educational necessity long felt by the profession of the State. It was formed under a resolution of the Academy of Medicine of this city, and received the unqualified endorsement of the State Medical Society.' At present the college forms the medical department of the State University, and has, therefore, every endorsement of respectability, so far, at least, as the outer world can judge. Yet tuition in it is offered free, and attendance only on a single lecture course of about four months' duration is required for graduation. The session opens on October 12, and closes on February 26: whilst the official announcement expressly states, 'Four years of reputable practice are considered equivalent to one course of lectures.' We note these facts not to complain of them, but simply as beacon-lights; not because the profession in this portion of the country is directly responsible for them, or able to change them, but because they are the legitimate and inevitable fruits of that system of medical education which was fastened upon the United States by the founders of the Medical Department of the University of Pennsylvania,—a system still supported by the example, if not the precept, of every medical teacher in the east, outside of Boston.

THE INFLUENCE OF AGE UPON SUICIDE.—The influence of age upon suicide is a study of more than speculative interest, on account of its practical bearings, and of the ease and precision with which it can be demon-

strated. By age is meant the critical periods of life. These periods having many components besides the mere fact of years, it is apparent that what we have to examine is a many-sided phenomenon, including together with it the advance in life, the workings of physiological, mental, and sociological causes. It has been lately examined by Dr. O'Dea, and it appears that the maximum of suicides for both sexes occurs between the ages of twenty-five and fifty-five. Previously to the twenty-fifth year there is a sudden increase from two suicides between the ages of five and ten, to one hundred and thirty-six between twenty and twenty-five. After fifty-five the tendency to suicide declines, but more gradually than it rose, except at sixty-five, where the number increases from eighty-one to eighty-three, a rise so slight, however, as to be little worth considering. There are, therefore, three suicidal periods in life; those of organic and mental growth, of organic and mental completion, and of organic and mental decline. In the first the chart shows 80; in the second, 942; and in the third, 311. Comparing the periods in round numbers, it may be said that they are as one for childhood and adolescence to twelve for adult life, and to four for the years of bodily and mental decay. The influence of sex and its attendant circumstances upon suicides at the different periods of life is shown upon the charts. With females, as among males, there is a sudden and abrupt rise until the twenty-fifth year is reached. This rise is continued to the thirty-fifth year, at which the maximum of suicides occurs among women. The period from the twenty-fifth to the thirty-fifth year corresponds to that of the greatest pressure from domestic troubles and responsibilities, and also with the greatest activity of the maternal functions. The line thence descends abruptly to the forty-fifth year, whence it rises to the fiftieth, the critical period of mature female life, and then goes down, down, until it reaches the level from which it started. There are, therefore, two culminating points, and whilst the line on the male chart is undulating and sustained, that on the female chart is vertical and abrupt. The lower of the male culminating points is the higher of the female, and contrariwise, the lower of the female is the higher of the male. These charts do not show the relative frequency of suicides among the two sexes. The ratio of suicides to population in the United States is (for the period covered by the last decennial census) 25 to 100,000 among males, and 3 to 100,000 among females. The only periods at which suicides are nearly equal for both sexes is from fifteen to twenty years, during which the number of boy-suicides was thirty-four, of girl-suicides, thirty-two. After this the number of suicides among males is much greater than among females.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17s. 4d.; free by post, 19s. 6d. Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each. Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & CO., London; and through their Agents.—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT. The First Volume, containing upwards of Two Thousand Articles abstracted and compiled by a staff of Fifty Hospital Surgeons and Physicians, is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for the year 1873 are also ready, price 1s. 6d. each. Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & CO.—Calcutta: THACKER, SPINK & CO.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & CO.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & CO., 10 Rue Castiglione. Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, DECEMBER 2, 1874.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

WARLOMONT, DE NEFFE, AND VAN WETTER ON THE INJECTION OF CHLORAL INTO THE VEINS AS A MEANS OF PRODUCING ANÆSTHESIA.*

The idea of producing anæsthesia in this way first originated with M. Oré, the Professor of Physiology in the School of Medicine at Bordeaux, on hearing the results of such injections in cases of acute tetanus, which had been communicated to the Société de Chirurgie at Paris. At the meeting in question, M. Verneuil said that he had known five cases of tetanus to recover under this plan, whereas he had never previously seen a single case recover; and M. Boinet had seen two cases recover out of four which had been treated in this way. Not content with this, however, M. Oré asserted his belief that 'injections of chloral by the veins ought to be preferred to the administration of chloroform by inhalation, in order to produce anæsthesia,' and the assertion was followed by a strongly worded protest from the members of the society. At the Académie des Sciences, the proposition fared no better; and lastly, at the Académie de Médecine, M. Vulpian declared that, having made a large number of injections of chloral into the veins of dogs in order to produce insensibility, he had on several occasions known severe hæmaturia to result. M. Blot and M. Gosse- lin both endorsed the sentence of condemnation which the Société de Chirurgie had passed upon the proceeding. In the opinion of M. Gosselin, 'the injection of chloral by the veins presents no advantages, although it is attended with much inconvenience and with some danger; the inconvenience is great, and the danger is real; for adhesive or suppurative phlebitis may occur, or coagulation of the blood; and there may be great difficulty in inducing insensibility, and a persistent restlessness may follow the attempt.'

M. Oré did not allow himself to be discouraged by this weight of disapproval, but by his repeated experiments he induced two other distinguished surgeons, MM. De Neffe and Van Wetter, to follow his example; the former of whom communicated to the Academy of Medicine of Belgium† an account of eleven operations which had been performed by M. Oré and by himself. These cases may be shortly described as follows.

Case 1. In a case of partial resection of the calcaneum, a fine trocar was inserted into one of the radial veins, and a solution of chloral, one part in three ('dix grammes pour trente grammes'), was slowly injected. When twelve grammes had been

inserted, the patient said he was very sleepy. There was no disturbance of the breathing, and the patient was quite calm. When twenty-two grammes had been injected, in less than ten minutes the most perfect insensibility was produced, which lasted during the entire operation, and which was not broken till after the application of powerful and repeated electric currents. It was the report of this case which had drawn forth the condemnation of MM. Gosse- lin and Vulpian, at the meeting of the Académie de Médecine.

Case 2. [This was a case of cancer of the rectum. An account of it was given in the LONDON MEDICAL RECORD for November 18, page 732.]

Case 3. A woman, aged forty-six, underwent an operation for the removal of the entire breast. The operation commenced at 3.45 P.M. on August 8, 1874. At 3.47 the trocar was inserted into the median basilic vein of the left arm, and the injection of the usual solution of chloral began, and was slowly continued. At the end of seven minutes, when four grammes had been injected, the insensibility, with the exception of that of the conjunctiva, was complete. In another minute, the injection of another gramme sufficed to bring about complete insensibility of the entire body. The operation was a large one, and involved the removal of the entire breast, of the great pectoral muscle, and also of a mass of diseased axillary glands; there was severe hæmorrhage, which required the free use of the actual cautery; and it occupied about an hour in its performance. During the first quarter of an hour the insensibility might have been that of a corpse, but after that there were complaints and reflex movements. A profound sleep lasted for seven hours, at the end of which the patient complained of thirst, but recognised nobody, and immediately sank again into a heavy sleep, which continued till early the following morning. Sensibility was not completely restored till the end of twenty-four hours, at the end of which time the patient first complained of pain. Throughout the entire proceeding there was no disturbance of the respiration or of the circulation. The puncture of the vein was followed by no sign of irritation; and the urine which was passed after the operation contained no trace whatever of blood.

Case 4. Injection was made, on account of fatness of the patient, into one of the veins immediately above the wrist of a woman, aged seventy-one, and the whole of one of her breasts was removed. Rather more than five grammes of the solution were injected, and at the end of six minutes insensibility was complete; this lasted for half an hour, and was followed by profound sleep for the next twelve hours.

Case 5. For an operation on the breast of a young woman, aged twenty-one, the injection was made into the median cephalic vein. Six grammes were injected; the insensibility was complete in eight minutes, and lasted for sixteen minutes, being followed by sleep during ten hours.

Case 6. In an operation upon a young woman, aged twenty-two, for abscess in the right ischio-rectal fossa, six grammes were injected into the median cephalic vein. In eight minutes insensibility was complete; it lasted forty minutes, and was followed by sleep for nineteen hours.

Case 7. In an operation upon a man, aged forty, for recurrent cancer of the testicle, 120 grammes of water, holding in solution twelve grammes of chloral, were injected into the left internal saphena

* *Annales d'Oculistique*, September, October, 1874.

† *Académie de Médecine de Belgique* (Bull. tome viii, 3^e série, No. 7 et 8, p. 816).

vein. Insensibility was complete in seven minutes, and remained so for three hours; it was followed by sleep during twenty hours.

Case 8. In an amputation of the toe of a man on account of enchondroma, six grammes of solution of chloral were injected into the median basilic vein. Insensibility was produced at the eleventh minute.

Case 9. In an enucleation of the eyeball on account of sympathetic ophthalmia, six grammes of solution were injected in nine minutes, at the end of which time insensibility was complete.

Case 10. This was one of extraction of cataract in a man, aged seventy-four, who was suffering extremely from chronic bronchitis with emphysema. In thirteen minutes nine grammes of solution were injected; complete insensibility was produced without any sign of danger, and without any difficulty whatever.

Case 11. Nine grammes of solution were injected into the median basilic vein of a man, aged thirty-eight, on account of caries of the tibia. Insensibility was produced in twelve minutes, and was followed by sleep for twenty-four hours.

The solution recommended is that of one part of chloral to three of water, so that from five to fifteen grammes of hydrate of chloral may be injected; and the injection is to be continued till there is absolute insensibility of the cornea.

The injection may be performed with any of the various kinds of apparatus which have been employed for the operation of transfusion. The syringe recommended for this purpose by Dr. Jos. Casse (*De la Transfusion du Sang*: Bruxelles) is said to be very convenient. A ligature is applied to the arm to ensure a projection of the vein to be punctured, and a vein situated as far as possible from the heart should be chosen. The first thing to be noticed is an inclination to sleep on the part of the patient, and sometimes a feeling of faintness. Insensibility generally commences after the first five minutes, and is complete before the end of ten minutes. Four grammes of chloral are generally sufficient to produce a very decided effect.

The period of insensibility is generally succeeded by a calm sleep, which is rarely broken, and which may last for many hours.

The authors assert that their method of proceeding has the following advantages.

1. Complete insensibility may be produced as rapidly as can be wished, without any resistance on the part of the patient.
2. An exact dose may be employed.
3. It is possible to regulate the period of insensibility, and also the succeeding period of calm sleep.
4. The sleep which succeeds is of great value to the patient as a period of repair.
5. There is no period of excitement, and no subsequent vomiting.

They consider the proceeding especially applicable when it is not advisable to give chloroform or ether in the ordinary way; when, for instance there is disease of the lungs, or when the patient is refractory, in operations about the mouth, or the nose, or the respiratory organs; in all cases where a period of after-repose is called for; and they think it of especial value in all cases of extraction of cataract, in consequence of the absence of subsequent sickness.

Dr. Warlomont is unwilling to believe that this plan of injection can ever be anything but accessory to the ordinary method of producing anaesthesia by inhalation, but he admits that the experience of the

above eleven cases tends to show that some of the risks attending injections of chloral, such as coagulation of the blood and the formation of clots, a paralyzing action upon the heart, etc., are not so imminent as has been supposed.

BOWATER J. VERNON.

PREVENTION AND TREATMENT OF PUERPERAL DISEASES. BY DR GOODELL, OF PHILADELPHIA.

(Concluded from page 741.)

The arguments against the customary purge on the second or the third day are to my mind very sound. I am well satisfied that the 'milk-fever,' for which it was originally introduced into practice, is essentially a myth. Genuine 'milk-fever,' as such, is a rare complication, and, when present, of no significance whatever. Unless the nipples be chapped or abraded, the engorgement of the breasts hardly ever leads to abscesses. In proof of this assertion, how rarely does mastitis follow still-birth! In the vast majority of cases, the occasional constitutional disturbance, the chill-and-fever on the third or fourth day—the so-called 'milk-fever'—is owing to a septic cause, and not to a mammary one. True, the breasts are by this time swollen and painful, but it is a mere coincidence, and coincidence is here mistaken for causation. Purges are, therefore, not only wholly unnecessary, but they disturb the equilibrium, and, what is worse, promote the absorption of septic matter. Partly from increasing the activity of the absorbents, the hæmorrhages of labour are very liable to be followed by blood-poisoning. Now, the same result may be logically predicated of a depletion in the shape of a purge. Were my readers to go over their cases of puerperal fever or of other puerperal diseases, I think that they will find some of them dating from the day on which a purge had begun to act. Is it not more than a mere coincidence that these diseases attack a woman usually on the third or the fourth day—viz., the day of or following the administration of the customary purge? Three instances of puerperal peritonitis, two of them ending in death, have come to my knowledge, which were referable as plainly as could be to purgation. In one, the lady was slowly but surely mending from the effects of a severe instrumental delivery. For some reason or other she took, in the third week, an ordinary dose of citrate of magnesia. This violently purged her, and at once brought on a fatal attack of fever. In the other two the patients could not have been doing better, until they got a dose of castor-oil, which was given for no other reason than that the authors of our text-books were haunted by the bugbear of 'milk-fever.' Did space permit, I should like to show that this opinion is not shared by myself alone; that cases of phlegmasia dolens have been traced to the effects of a purge, and that the use of aperients during an epidemic of puerperal fever has been strongly condemned.

Quinia is given without stint, because, apart from its well-known tonic and antiperiodic properties, it possesses others which make it, above all remedies, the one best suited for puerperal disorders. By lowering high temperature it retards the oxidation of tissue, and hinders the formation of fibrinous concretions. By shortening the excursions of uterine fibres in their alternate contractions and expansions, it lessens the diastolic engorgement of the womb,

diminishes the calibre of the uterine blood-vessels, and thereby tends to keep their protective coagula from becoming loose and soluble. By contracting the placental site, it proportionally limits that area of absorption. By constricting the coats of the capillaries, and by its inhibitory power over the migration of colourless blood-corpuscles, it either arrests suppurative inflammation or restrains its violence. Finally, it seems to exert a positive curative action on the blood in cases of putrid or purulent absorption. Clinically, I have found nothing comparable to quinia as a prophylactic against puerperal disorders, as well as a remedy for them. But it must be given early, frequently, in large doses, and pushed to a high grade of cinchonism.

Ergot is a very untrustworthy oxytocic. One never can tell beforehand whether it will behave kindly, or run a muck. It is, therefore, no favourite with me. The vectis and the forceps, being under perfect control, are far better oxytocics; their aid is therefore often invoked, in order to save a woman's strength, and to avoid that laxness of uterine fibre following a long and weary labour. Ergot is, however, given as the head is about to emerge, in order to lessen the chances of a flooding or of unruly after-pains, and to aid the process of involution by condensing the uterine globe to its minimum size. For an analogous reason I feel persuaded that Credé's method of placental delivery provokes to a more complete involution. It certainly empties the womb of all clots, and squeezes it down to its smallest capacity.

The prolonged use of the binder is given up. Even its brief use during the first few hours after labour is not held by me as a cardinal point. I begin to have grave doubts whether it is of any value whatever in the prevention of hæmorrhage. On the score of utterly abandoning it, I am quite open to conviction.

So much for the reasons on which the foregoing measures are based. Let me now give the results. Up to date there have been 756 cases of delivery, with six deaths. The following are the order and the numbers of the fatal cases, as copied from the Case-Book.

'No. 22. Concealed accidental hæmorrhage from the gravid womb. No. 203. Puerperal peritonitis. No. 289. Acute chorea. No. 360. Caries of petrous portion of the temporal bone. No. 398. Chronic pelvic abscess. No. 647. Septic pneumonia.'

The case of puerperal peritonitis was an isolated one. The woman had been abandoned by her husband, to whom she was devotedly attached. She fretted and brooded over this desertion in so despairing a manner as to make me apprehensive of mania. Three other patients occupied the same ward with her, but they escaped from contagion.

Cases 22, 289, and 360 were deemed by me so exceptional that their histories were reported to the Obstetrical Society of Philadelphia, and afterwards embodied in its Transactions (*Am. Journal of Obstetrics*, vol. ii. p. 286; vol. iii. p. 140; vol. iv. p. 126). Case 398 was that of an old pelvic abscess following a previous labour—viz., an abortion produced by the kick of a drunken husband. During the last week of utero-gestation, this abscess began to inflame and to cause so much suffering that very large doses of morphia were needed to control it. Labour very greatly intensified this distress. When the womb was emptied, a tumour was found in the left broad ligament, and all the symptoms of localised peritonitis were present. Under appro-

priate treatment the patient soon began to mend; but on the fourteenth day she was suddenly seized with violent abdominal pain, and fell into a collapse, from which she never rallied. A necropsy revealed an old pelvic abscess, which had burst into the cavity of the abdomen. This case, it seems to me, cannot fairly be attributed to a septic cause, but to the *ante partum* recrudescence of an old lesion. Case 647 is one of doubt in my mind. There were no appreciable pelvic or abdominal lesions; and yet, in default of a necropsy, which was not permitted by her friends, I think it fairer to attribute the pneumonia to blood-poisoning rather than to a non-septic cause.

To sum up then, out of 756 cases of labour there have been two deaths from septic causes; 1 death from the bursting of an old abscess; 1 death from hæmorrhage; 2 deaths from non-puerperal diseases.

Apart from the above record, the Case-Book exhibits no case of phlegmasia dolens, and none of pelvic abscess. One woman, however, had, I am told, a pelvic abscess at home. Through fright at an outbreak of measles in the building, she insisted on rising from her bed and on being discharged on a wet winter night. Although a large proportion of the inmates were primiparæ, and two of them confirmed epileptics, but two cases of eclampsia took place, and these in women who had not been subjected to any prophylactic treatment. The one, while labouring under violent convulsive attacks, was brought in a hack by her friends; the other was seized the day after admission. Both recovered under repeated rectal injections of drachm-doses of the hydrate of chloral, and a final delivery under ether with the forceps.

Since nothing is so fallacious as statistics, even when based on large averages, it is with much diffidence that I offer the above meagre data. They may not sustain my views; but they will, I hope, show that lying-in women can be gainfully treated in a manner less artificial than is customary, and more in accordance with the maxim *naturâ duce*.

One word more: For many reasons the statistics of a lying-in hospital can never compete with those of private practice. Of these I shall adduce but two. In the first place, the former are most trustworthy, for physicians very naturally shrink from reporting their fatal midwifery cases as such. I have known a death from *post partum* hæmorrhage returned as one from 'anæmia,' and another from puerperal albuminuria as a case of 'pneumonia'—œdema of the lungs being present; whilst fatal cases of puerperal septicæmia are constantly being certified to under the heading of some prominent symptom which tells no tale, such as 'peritonitis,' 'pleuritis,' or 'pneumonia.' For instance, during a period of eight weeks of this year, I was asked to see eight cases of puerperal fever,—four of them from one Sunday to another. Of these all but one proved fatal. During the same time I casually became cognisant of seven other fatal cases. Now, during those eight weeks I studied with much interest the weekly returns of the Board of Health, and found there reported just twelve deaths from 'puerperal fever.' There were, however, also reported eleven deaths from 'inflammation of the peritoneum,' one death from 'child-bed,' and one each from 'septicæmia' and 'pyæmia.' Comment on the above is unnecessary; the figures speak for themselves. In the second place, physicians naturally avoid the worry and anxiety, the delay and trouble

incident to difficult labours, in their private practice, especially when such occur in a class from which they can expect no adequate remuneration. A hospital thus becomes the Cave of Adullam for all these abandoned cases. For instance, out of the six fatal cases which I have reported out of the case-book of the Retreat, the one of chorea and that of hæmorrhage were sent to the institution by the family physician,—the former on account of her being unmanageable at home, the latter because her labours were growing more and more difficult from an exostosis. The two epileptics* alluded to, two distressing cases of phthisis and valvular disease of the heart, and many of difficult labour in multiparæ, come under the same category. There are at present in the building two women not yet delivered, who were sent thither by their respective medical attendants. The one is an epileptic primipara; the other is a secundipara with a vesico-vaginal fistula—the result of craniotomy in her previous delivery. It is thus that the death-rates of lying-in hospitals show to disadvantage beside those of private practice.

THE CHEMISTRY OF CREMATION.†

In a paper recently published in a German periodical on the chemical bearings of cremation, Professor Mohr, calls attention to a point which, so far as we know, has not yet been considered.

He remarks that, in the first place, it is necessary that the combustion of the body should be complete. Anything of the nature of distillation gives rise to the production of fœtid oils, such as were produced when in early times dead horses were distilled for the manufacture of sal-ammoniac. Such a revolting process is surely not compensated by the small commercial value of the products obtained. To effect complete combustion, we must have a temperature such that the destruction is final, nothing remaining but carbonic acid, water, nitrogen, and ash; for which purpose a complicated apparatus consuming large quantities of fuel will be necessary. The gases produced can only be destroyed by being passed through red-hot tubes to which excess of atmospheric air can gain access.

On comparing the substances produced by such a total decomposition of the body with those produced in the ordinary course of subterranean decay, it will be seen that one compound is totally lost by burning, the ammonia which results from the decomposition of the nitrogenous tissues. This ammonia, escaping into the air or being washed into the soil, is ultimately assimilated by plants, goes to the formation of nitrogenous materials, and thus again becomes available for animals. In the ordinary course of nature a continuous circulation of ammonia between the animal and vegetable kingdoms is thus kept up; if we stop one source of supply of this substance we destroy the equilibrium, we draw upon the ammoniacal capital of the globe, and in the course of time this loss cannot but react upon animal life, a smaller amount of which will then be possible. There is no compensating process going on in nature, as is the case with the removal of atmospheric oxygen by breathing animals; we deduct from a finite quantity, and the descendants of present races will, in time to

come, have to bear the sin of our shortsightedness, just as we have had to suffer through the shortsightedness of our ancestors, who destroyed ruthlessly vast tracts of forests, thereby incurring drought in some regions and causing destructive inundations in others.

Another loss of ammonia is entailed by civilisation in the use of gunpowder. Nitre results from the oxidation of ammonia, and is a source of nitrogenous compounds to plants, which again reduce the nitrogen to a form available for ammonia. The nitrogen liberated by the explosion of gunpowder adds to the immense capital of the atmosphere, but is no more available for the formation of plants. Every waste charge of powder fired represents a certain loss of life-sustaining material against which the economy of nature protests. The same is to be said of nitroglycerine, gun-cotton, etc., which contain nitrogen introduced by the action of nitric acid.

Wood and coal are other illustrations of finite capital. Every pound of these substances burnt in waste—consumed, that is, without being made to do its equivalent of work—is a dead loss of force-producing material, for which our descendants will in the far-distant future have to suffer. The changes brought about by the cessation of one large supply of ammonia may be compared with geological changes, which, though of extreme slowness, produce vast changes in the lapse of ages.

ANATOMY AND PHYSIOLOGY.

BADAUD ON THE INFLUENCE OF THE BRAIN ON THE BLOOD-PRESSURE IN THE PULMONARY ARTERY. Dr. Badaud (*Verhandlungen der Phys.-Medicinischen Gesellschaft zu Würzburg*, Band viii. p. 1) has investigated this subject in Fick's laboratory. The blood-pressure was not measured directly in the pulmonary artery itself, but was estimated from the pressure in the right ventricle, the pressure during the cardiac systole being the same in the right ventricle as in the pulmonary artery. As the results would have been much disturbed by the operation of opening the thorax, the pressure in the ventricle was ascertained by means of a catheter passed into it through the jugular vein, and connected with a new manometer of peculiar construction invented by Professor Fick. This manometer consists in a glass tube, about half an inch in diameter. One end of this is open, the other is closed by a thin membrane of caoutchouc, on which is glued a round piece of wood, which almost exactly fits the tube, and is kept firmly pressed into it by a strong spring. When the instrument is connected with an artery by means of a rigid tube, the pressure inside forces up the wooden plate and spring, and their movements are magnified by a long lever in much the same way as those of the spring in Marey's sphygmograph. The advantages of this instrument are that it does not alter the quantity of blood in the artery with which it is connected, and that it registers rapid movements with great precision. Their experiments showed that the pressure in the pulmonary artery is very much less than in the aorta, the former in one experiment being 48 millimètres of mercury and the latter 102. When the spinal cord is cut the pressure sinks in both, but so much more in the aorta than in the pulmonary artery, that it becomes almost exactly the

* I am not aware that epilepsy predisposes to puerperal eclampsia—at least I have not found it to do so. But many physicians look upon it as a dangerous complication in labour.

† From *Nature*.

same in both. In the experiment just mentioned it became 18 millimètres of mercury in the pulmonary artery, and 20 in the aorta. This result may be thus expressed. After section of the spinal cord, the right ventricle does exactly the same work at each systole as the left.

When galvanic irritation is applied to the spinal cord after its division, the pressure rises in both the pulmonary and systemic vessels. In one experiment it rose in the pulmonary vessels from 18 to 84 millimètres, and in the aorta from 23 to 87. In another it rose in the pulmonary vessels as high as 108 millimètres. The rise in tension during irritation of the cord is therefore much greater in proportion to the normal pressure in the pulmonary artery than it is in the aorta. Irritation of the splanchnics raised the pressure in the pulmonary artery very slightly; so the rise during irritation of the cord could be due only in a very slight degree to the blood forced into the venous system by the arterial contraction. Compression of the aorta did not raise the pulmonary tension; so the increased circulation through the coronary arteries has nothing to do with the rise in pressure during irritation of the cord.

All these facts show that the pulmonary arteries are kept in a state of tonic contraction, and the right ventricle is regulated by the central nervous system in the same way as the systemic vessels and left ventricle. The tonus in the pulmonary is much less than in the systemic arteries. Irritation of the nervous paths leading to the heart and vessels causes the latter to contract, and makes the former pulsate both more frequently and more strongly. The form of the curves obtained shows decisively that irritation of the accelerating nerves of the heart in the spinal cord renders the beats of the heart more forcible as well as more frequent. [The probable existence of vaso-motor nerves for the lung in the two spinal roots of the first thoracic ganglion was deduced by Schmiedeberg from his experiments in Ludwig's *Arbeiten*, 1871, p. 40.—*Rep.*]

KUNKEL ON THE GASES PRODUCED DURING ARTIFICIAL PANCREATIC DIGESTION.—Dr. Kunkel (*Verhandlungen der Phys.-Medicinisches Gesellschaft zu Würzburg*, Band viii.) finds the following results.

1. In artificial pancreatic digestion of pure fibrin, by means of the pancreatic gland cut small under glycerine, carbonic acid, hydrogen, hydrosulphuric acid, nitrogen, and marsh-gas (CH_4), appear, and traces of other hydrocarbons. 2. The proportion of carbonic acid increases, and that of hydrogen diminishes with the duration of the experiment. 3. Hydrosulphuric acid and marsh-gas only appear towards the end of the experiment. 4. Nitrogen is present in small quantity. It is not due to admixture of atmospheric air. 5. Oxygen was never to be found.

T. LAUDER BRUNTON, M.D.

BÖHM ON RESUSCITATION AFTER POISONING.—R. Böhm, of Dorpat, has made the observation (*Centralblatt für die Medicinischen Wissenschaften*, no 21, 1874), that the action on the heart and nervous system of warm-blooded animals, which is produced by doses of the salts of potash, which till now have been held as fatal, can be removed. When injected directly into the blood of a strong cat, 0.1, and 0.2 gramme of a potash-salt produce rapid sinking of the blood-pressure and arrest of the heart's action; in a few seconds the respiration ceases, and the animal dies in convulsions. If within

an interval, whose duration must not exceed eight minutes (reckoned from cessation of the respiration), artificial respiration be performed, and a moderate compression of the thorax in the region of the heart exerted during passive expiration, then the heart, after a pause in its action which may reach the long duration of forty minutes, begins suddenly to again pulsate regularly. With the restitution of the heart's action, the blood-pressure, which had sunk to the abscissa, reaches in a short time a level which in many cases exceeds the normal. First, from three to five minutes after the beginning of the heart's action, spontaneous respiration returns; then, from three to ten minutes after this the reflex excitability returns, and the animal conducts itself completely like a normal non-poisoned one. The experiment never succeeds where either the artificial respiration or the compression of the thorax have been too long neglected. As in all the experiments the blood-pressure was measured, it was shown that by each compression of the thorax a variation of from thirty to sixty millimètres of mercury was occasioned in the otherwise absolutely quiet arterial circulation. From a practical point of view it is of the greatest importance to observe, that artificial respiration alone (by the tracheal cannula) was never sufficient to produce the result; compression of the thorax was always required in addition. The explanation of these phenomena the author leaves for the present undecided.

WILLIAM STIRLING, D.Sc., M.B.

POLITZER ON THE ANATOMY OF THE EAR.—At a meeting of the Medical Society in Vienna, in the beginning of October (a report of which is given in the *Allgemeine Wiener Medizinische Zeitung* for October 20), Professor Politzer gave the result of some investigations which he had recently made into the anatomy of the ear. He finds that, in newly born children, the cavity of the pyramid containing the stapedius muscle is separated only at the upper part by osseous tissue from the canal through which the facial nerve passes, while the lower part of the cavity communicates freely with the same canal, and thus allows, at this spot, the muscle and nerve coverings to come into actual contact with each other. In the adult, the amount of direct communication between the cavity and canal is very various, ranging from a small opening sufficient for the passage of the nerve to the stapedius, to a large irregular opening. The styloid process, he avers, arises from a cartilaginous body, which not only in the foetus, but also in the newly born, is to be found as an isolated cartilaginous formation; and the upper end of the process does not terminate at the external visible base, but passes through a thin osseous lamella along the posterior wall of the tympanic cavity, reaching as far as the eminentia stapedii. In the adult, the process is sometimes solid, sometimes hollow, but generally there is a cellular structure with or without a central canal.

MEDICINE.

BORELLI ON THE PHYSICAL DIAGNOSIS OF INTERSTITIAL HEPATITIS.—Dr. Borelli (*Verhandlungen der Physikalisch-Medizinischen Gesellschaft zu Würzburg*, Band viii.), considers a constant sign of this disease to be a rise of the upper margin of the hepatic dulness, while the under margin remains at or very slightly under the normal position. In other diseases the under margin descends first, and the dulness only begins to extend upwards after the liver has become considerably enlarged. The cause of this is partly the meteorismus, which drives the liver upwards in this disease, and partly the non-resistance of the diaphragm, weakened by extension of the inflammation to it from the liver. Ascites does not usually occur during the neoplastic phase of the disease, but generally commences when the newly formed connective tissue begins to shrivel and to press on the hepatic vessels.

T. LAUDER BRUNTON.

HEYNSIUS ON A CASE OF DILATATION OF THE STOMACH, WITH ERUCTION OF INFLAMMABLE GAS.—In no. 37 of the *Nederlandsch Tijdschrift voor Geneeskunde* for 1874, Dr. A. Heynsius relates a case of a similar kind to those described and commented on by Drs. Schultze and Ewald (see LONDON MEDICAL RECORD, August 12 and 26). Dr. Heynsius was some time ago informed by one of his friends that an acquaintance of his from time to time caught fire. He said that the patient suffered from violent eructation after eating, and that gas was thereby discharged, which caught fire when a flame was brought near, as in lighting a cigar. This had taken place four times; on two occasions it produced rather severe burns, once of the mouth and lips, and another time, when the gas was mostly discharged through the nostrils, of the nose.

On seeing the patient, Dr. Heynsius found him to be a tolerably well-nourished man, aged thirty-five, a clerk by occupation. He stated that for ten or twelve years he had been much troubled with pain in the stomach. The pain was constant, sometimes more, sometimes less severe; and was not relieved by any medicines. Vomiting first occurred five years previously; in 1872 it was very severe, and was accompanied with violent pain in the back and both sides. At that time, the stomach was several times washed out with the stomach-pump; but this rather increased than relieved the symptoms. Since that time the vomiting had occurred sometimes twice a-day, sometimes scarcely twice a-week. The vomited matter was always of a very sour taste, never bitter; it was frequently found to contain food which had been eaten some days previously. He had never seen blood in it. Along with this, he was constantly troubled with a sense of distension in the gastric region, and with violent and offensive eructation. Four years ago, he had just lighted a cigar, when a discharge of gas from his mouth took place, and caught fire. The flame gave little light; it was about as large as the palms of two hands, and the burning was attended with a distinct, though not loud, explosive report. This subsequently happened three times. He had since avoided being very near a flame; when he smoked, his wife lighted his cigar for him. He further said that his bowels had been sluggish, and the fæces hardened. At one time, the

fæces were of a dark colour; but he thought that this occurred when he was taking iron.

Up to the present time the patient had looked fairly well, and had been able to attend to his daily business, which was not very onerous. He thought that he had lost weight in late years, but there was no emaciation of importance. He was of middle height, and well formed. The belly was protruded, especially on the left. The lower ribs on the left side were pushed forwards and outwards. On careful inspection, a bulging was observed extending from the lower part of the left side of the chest downwards, and to the right as far as the umbilicus, ending about four-fifths of an inch to the right of the linea alba. The whole abdomen was tympanic on percussion; on the left side, however, the intestinal percussion-sound could be plainly distinguished from the fuller stomach-sound, which began between the fifth and sixth left ribs, and extended downwards to about an inch and a half below, and about two and a half inches to the left of the navel. The liver-dulness began in the nipple line, at the sixth rib.

On succussion, a splashing sound was heard in the abdomen. There was no trace of tumour.

The patient still vomited frequently. He had no pain in the stomach, but an uncomfortable sense of distension after eating, which was relieved by vomiting or eructation. Meat and milk were ill borne, beef worse than pork; fish, bread, eggs, and butter-milk were much better tolerated; the use of butter appeared to give no trouble.

The case was evidently one of considerable dilatation of the stomach, probably the result of a stricture of the pylorus. That the obstruction was lower down was improbable, as the vomited matter never contained bile, and it was evident that the bile had a free passage downwards, as the fæces were always coloured. No decision could be arrived at with certainty as to the cause of the constriction.

After referring to the cases of Popoff, Frerichs, Schultze (and later on of Ewald), Dr. Heynsius says that his endeavours to collect the gas discharged by eructation failed. The patient, who still attended to his business, was at home only a few hours in the day. The chief difficulty, however, was that eructation generally took place very quickly, so that he had not time to apply the tube for collecting it to his mouth. Dr. Heynsius was, therefore, obliged to content himself with an examination of the vomited matter. The reaction was very acid; and, on standing, a separation into three layers took place. The uppermost layer consisted of thick froth, in which the remains of the meal were recognised (the patient had eaten cauliflower, sausage, and potatoes). The middle layer consisted of a semi-transparent yellow fluid. The lowest consisted of a grey granular mass, also containing *débris* of food.

Microscopic examination discovered the remains of food (fat-drops, muscular fibres, vegetable cells, starch granules); as well as an abundance of *sarcina ventriculi* and a not very great amount of *torula cerevisia*.

An examination of the vomited matter was made four hours after its ejection. In the meantime (it was warm weather) the process of fermentation had gone on, and the gas developed had driven the stopper out of the bottle. The vomited matter was raised to a temperature of 95° Fahr., and the gas was collected over mercury. That which first came over contained in 100 volumes, 78 of carbonic acid and 19.2 of hydrogen; while in some

subsequently collected the quantities were, carbonic acid 85.5, hydrogen 13.9. No marsh-gas could be found.

Much more carbonic acid and less hydrogen were present than was discovered by Popoff and Schultze in the gases discharged by eructation. The greater amount of hydrogen in the gas first collected rendered it probable that a still greater proportion of this gas would have been found, if it had been possible to make the examination immediately after vomiting took place. In the distillate from the vomited matter, butyric acid was found.

There could be no doubt that the phenomenon described in this case depended essentially on butyric acid fermentation, and that the hydrogen thereby developed was the cause of the inflammability of the ejected gas. The development of hydrogen probably takes place to a greater or less degree in various affections of the stomach.

In the treatment, temporary relief only was obtained by washing out the stomach with the stomach-pump. Creasote, carboic acid, quinine, and hypermanganate of soda had little or no effect in arresting the process of fermentation. On the other hand, improvement was obtained by the use of chlorinated water. A. HENRY, M.D.

PHILBERT ON THE TREATMENT OF OBESITY AND POLYSARCIA.—Obesity is, like gout, scarcely a hospital disease, for in general the poor do not suffer from it. Systems of medicine scarcely allude to it: nevertheless, it is a disease that may result in death.

A young physician, M. Philbert, relates (according to an analysis of his brochure of the above title in *La France Médicale*, November 4) his own case, and the treatment which has proved successful in it. At the age of twenty-six he weighed 24 stone, and his girth round the abdomen was 59 inches. His sleep was heavy, his pulse was regular, 72 beats. The action of his heart was natural, and the sounds a little dull; the appetite good, digestion quick, bowels regular; there was great tendency to perspiration, especially at night. On July 15, 1869, he consulted Dr. Labat, who sent him to Marienbad, to the care of Dr. Schindler, who ordered him to rise at six A.M.; between six and half-past seven to drink three glasses of about 7 oz. each of the Kreuzbrunnen spring. At the end of three weeks, half a tea-spoonful of the salt extracted from the water was added. Between seven and half-past eight he had the first breakfast, of two boiled eggs, a cup of tea, and a small roll of bread. The action of the water produced in the course of the morning two soft motions. From nine to ten o'clock he had a vapour-bath every second day, during the first three weeks; after that period, one every day. This bath was given after the following fashion: after sweating was established, friction with a glove, and then a douche of cold water: second sweating, friction with a soft brush: third sweating, stimulation of the skin by flogging it with a birch made of small twigs of poplar with their leaves on, and after this a last douche of cold water (this, after the fashion of the Russian bath): after leaving the bath, friction with vinegar of pine-sprouts: promenade after the bath. At eleven o'clock he had a second breakfast, consisting of two plates of meat or fish, one of vegetables, a *compote* without sugar, half a bottle of wine, and two small rolls of bread. From midday to six in the evening he was ordered to stay in the forest and take as long walks

as possible, without inducing fatigue. At six o'clock he had a dinner of one plate of cold meat, a *compote*, a half bottle of wine and a roll of bread: after dinner, a promenade. At eight o'clock he was shampooed with soap. At half-past eight he went to bed, and had cold compresses applied over the stomach. At the same time, morning and evening, five reducing pills, as they were called, with an alkaline base, were given. This treatment was borne well, and lasted for six weeks. At first the patient walked with great difficulty; by degrees, as his weight diminished, exercise became easier; there was sleepiness, but in a less degree. The thirst, which was excessive at first, diminished gradually; when it was urgent at meals, some lemonade was allowed. At the end of the first week there was a loss of weight of 12 lbs., at the end of the second of 2 lbs., at the end of the third of 6 lbs., at the end of the fourth of 8 lbs., at the end of the fifth and sixth of 7 lbs. each; altogether 42 lbs. in six weeks.

In the middle of September, M. Philbert carried out for a fortnight with Marienbad water, at home, a course identical with that just described, and continued to become thinner. He then went to Fontainebleau to try the grape-cure, which consisted in eating every morning, on an empty stomach, somewhat over 2 lbs. of grapes gathered from the vine, and in walking as much as possible. During the cure at Marienbad and at Fontainebleau all uncooked vegetables and fruit were avoided, lest they should bring on diarrhoea. By November 7th the weight was reduced to 20 stones, and at present the patient weighs only 14 stones, is in excellent health, and his embonpoint attracts no observation.

The most strikingly successful part of this treatment is the action of the waters of Marienbad. The chief constituents of a pint (sixteen ounces) of the Kreuzbrunnen are, sulphate of soda 38 grains, chloride of sodium, 13 grains, and about the same amount of carbonate of soda. The vapour-baths also are a powerful adjuvant. Although stout people usually belong to the higher classes, and can afford to travel abroad, yet there is no reason why they should not try a cure at home, by taking $1\frac{1}{4}$ drachm of sulphate of soda every morning fasting; or they may try various French purgative or laxative springs, such as Brides, Chatel Guyon, Rouzat, Saint-Nectaire. [Of these I have little doubt that Saint-Nectaire, with the addition of a little sulphate of soda, would answer admirably.—Tr.]

The principal measures for reducing obesity, come under four heads: 1. *Régime*; 2. Hygiene; 3. Exercise and Gymnastics; 4. Waters with sulphate of soda. The basis of the *régime* rests on the prevention of the introduction of carbon into the system, or on favouring its transformation, and augmenting the amount of oxygen. The food must, therefore, be non-nitrogenous, varied with a few vegetables containing no starch, and some raw fruit. But the temperament of the patient must be kept in view. The lymphatic should have a red diet, beef, mutton, venison, hare, pheasant, partridge, etc., and the sanguine should have a white diet, veal, fowl, pigeons, oysters, etc. Vegetables, not sweet, or farinaceous, may be allowed: grapes, gooseberries, apples, etc. *Café noir*, tea with little sugar and the addition of a little cognac may be used. We must forbid sugar, butter, cheese, potatoes, pastry, rice, beans and peas, etc.

The hygiene consists in favouring the action of the skin, in wearing a tight roller to support the walls

of the abdomen, in taking plenty of exercise on foot or on horseback, playing at billiards, fencing, swimming, gymnastics, etc.

The Banting treatment is not very different. It consists in abstaining from bread, butter, milk, beer, potatoes, pudding, and from sugar in every shape. It allows some biscuit or dry bread, every kind of fish except salmon, and every kind of meat except pork, all vegetables except potatoes.

Purgatives have a good deal to do with the success of treatment of cases of obesity, and some have thought scammony as effective as sulphate of soda.

J. MACPHERSON, M.D.

DA COSTA ON STRAIN AND OVER-ACTION OF THE HEART.—In one of the Toner Lectures, delivered at the Smithsonian Institute, at Washington, in August, 1874, Dr. Da Costa adds his testimony to the rapidly accumulating mass of evidence showing the effects of strain upon the heart. He first deals with acute strain as compared to less rapidly acting causes. It is not in previously diseased hearts alone that acute strain causes rupture or tears; it is the consequences of such strain in hearts previously healthy that he considers. He gives cases where valves were torn from their attachments, as the consequence of violent effort. The valves which suffer most severely from such causes are the aortic and the mitral; but the same thing may happen to the tricuspid. From the cases given, it appears that such results follow great excitement as well as violent efforts. One case of fright, in a little girl of two years and nine months, resulted in death in seventy-eight hours. The right auriculo-ventricular valves were found to be lacerated and broken in their substance, as were also several of the columnæ carneæ, and chordæ tendineæ. He does not think that these cases can be explained on any hypothesis of a rapidly developed endocarditis. He is, however, inclined to believe that rupture of a valve is often connected with the existence of slight fissures in the valvular vela, which predispose to rupture.

After this, he proceeds to consider more persisting action and shows the connection of 'irritable heart' with excessive exertion combined with mental tension or with diarrhœa. The pulse is small, rapid, and readily compressible. Its rate is much reduced by the recumbent posture. The impulse of the heart is extended, abrupt; the first sound is short, the second very distinct. Occasionally the first sound is replaced by an inconstant murmur. The respiration is not hurried or frequent in proportion to the pulse. The general health often appears good, or at least it may be fully restored while the cardiac malady remains. Such cases Dr. Da Costa saw very frequently in the late civil war.

He is strongly of the opinion that a period of apparent functional disorder precedes the dilatation with hypertrophy which ultimately obtains, with or without accompanying valvular disease. 'Nay, in the light of these remarks, we can understand how even mental emotion, acting through the nervous system on the nerves of the heart, may produce real trouble, and how the worry of life and strain on the feelings, when long kept up, may give rise to conditions which, in figurative language, we call 'heart-weary' and 'heart-sick,' and which, not as a figure of speech, but in truth, may be the beginning of actual cardiac malady.'

He then goes over the physical causes of irritable heart. Excessive work in deep mines, entailing the

climbing of long ladders while carrying heavy loads, employment as bargemen, porters, strikers in iron foundries, are productive of disease, especially of the aortic valves. Glass-blowing he has found to be accompanied by much disease of the heart. Excessive dancing was the cause of disease in one case. Rowing, he considers, will do harm in many cases; and he advises that men intending to follow boating as their chief amusement should consult a careful physician ere commencing, and then have their hearts examined from time to time. He is averse from stopping athletics in consequence of the injurious consequences to some of the votaries. Finding heart-trouble induced in some men by baseball, he examined a number of baseball players, and comes to the conclusion, 'that as regards the effect on the circulation, all active, even violent exercise, is only injurious when too steadily persevered in; and that it is the intermitting which protects, and which is the cause why these exercises and pastimes are less productive of cardiac affection than the hurrying and impeding of the circulation, occasioned less palpably but more constantly, by certain occupations.'

As to the treatment of such cases, the first thing is to preserve general quiet. From the effects of the recumbent posture upon the heart, it is desirable that the patient rest on his back two or three hours a day, and an occasional day or two in bed materially helps. Ice to the chest is only desirable in very stubborn cases. Of medicines, digitalis, belladonna, and the bromides, are the most generally available. In cases of commencing hypertrophy, aconite, steadily employed, gives capital results. In any form of the affection, to remove the cause is a prerequisite for success. He concludes: 'Yet the greatest gain from the study of the subject, its most brilliant results, will come, if by the knowledge acquired of the production of heart-trouble we can prevent its increase. The public, in the matter, err from ignorance, and it is our place to show them that the heart will not, any more than the brain, endure incessant and exhausting labour and excitement; that there are heart-weary as well as brain-weary people; to point out how some occupations predispose to the disorder more than others; anyhow, therefore, the dictates of science, of humanity, and true economy, alike demand that they be less continuously pursued.'

J. MILNER FOTHERGILL, M.D.

SURGERY.

MCLEAN ON ANEURISM OF THE LEFT SUBCLAVIAN ARTERY CURED BY DISTAL LIGATION.—Mr. R. A. McLean reports (*Western Lancet*, July, 1874) the following case, which occurred in Dr. Toland's clinic at the San Francisco Hospital.

John Cross, aged fifty, a miner, was admitted on January 8, 1874, suffering from a large pulsating tumour at the root of the neck, on the left side. Its superior surface was limited internally by the sterno-clavicular articulation and anterior margin of the sterno-cleido-mastoid muscle, and externally by a point beneath the anterior border of the trapezius, just above its clavicular origin. In the interval between the sterno-mastoid and the trapezius, it formed an ovoid tumour apparently as large as the closed hand. Auscultation and palpation elicited the usual signs of subclavian aneurism.

The patient first noticed a slight enlargement above the clavicle a year before, but its progress had been slow until within two months prior to his admission. During this time it had increased rapidly in size. Partial paralysis of the left arm had occurred from pressure upon the brachial plexus, and pressure upon the thoracic duct, interfering with nutrition, had caused considerable anæmia. Tonic treatment and good diet were prescribed, and kept up until January 24. During this time the tumour continued to increase in size. Dr. Toland operated on January 24. He thought the Hunterian operation impracticable, as the tumour involved the first as well as the second and third parts of the vessel; and he accordingly selected the distal operation. The third portion of the axillary artery was chosen for the seat of the ligature. The artery was secured by double ligatures. The pulsation in the tumour was perceptibly lessened immediately after the ligature, and gradually decreased up to the sixth week from the date of the operation, after which no pulsation or bruit could be discovered. The ligatures came away on the twentieth day after the operation, and the wound healed a few days afterwards.

After the cessation of circulation in the tumour, it gradually grew smaller and less painful. The collateral circulation became fully established, the paralysis almost entirely disappeared from the arm, and the pressure upon the thoracic duct was evidently much less, as the patient gained considerably in weight. The left arm remained slightly œdematous, from pressure upon the subclavian vein. At the time of the report the tumour was at least one-third smaller than when the operation was performed. It was hard to the touch, and was evidently being rapidly absorbed.

Hitherto, cases involving such extensive disease of the artery, have usually terminated fatally. The Hunterian or proximal operation was deemed impracticable on account of the deep situation of the healthy portion of the vessel and the large size of the tumour, which of itself would have proved an insurmountable obstacle, covering as it did the route by which the vessel might have been reached in a case not involving so great a degree of disease of the artery. Galvano-puncture and the distal ligation remained as the last resort. The latter was chosen with the view of resorting to galvano-puncture if Brasdor's operation failed. It happily succeeded, and this, with a former case of Dr. Toland's, are the only successful cases recorded of the distal ligation for the cure of subclavian aneurism. Gross has collected twelve cases of ligation of the subclavian artery in the first portion of its course, and seven cases of the distal ligation of various arteries for the cure of subclavian aneurism. Death resulted in seventeen out of nineteen of these cases, from hæmorrhage; the seat of the hæmorrhage being, in nearly every instance, at the distal side of the ligature. It seems reasonable to suppose that this accident might have been avoided in at least some of the cases, if the double ligature had been used. In single ligation the proximal side of the vessel does not generally slough, because the point of ligation is at the junction of the sheath and artery, thus leaving the nutrition of the vessel uninterfered with. The sloughing occurs on the distal side of the vessel; and as that end of the artery remains patulous, hæmorrhage is the result. The reason for this is apparent, when we consider that the denuded portion of the artery is deprived of its channels of nutrition

through the vasa vasorum, to an extent varying with the degree of laceration of the sheath. This result is well illustrated in two cases in which the subclavian was tied on the inside of the scaleni muscles. The first was the case of Dr. Rodgers, in which death occurred on the fifteenth day from hæmorrhage. The other was the case of Professor Parker, death resulting from hæmorrhage on the forty-second day.

When the double ligature is practicable, the advantage is that the denuded portion of the artery between the two ligatures sloughs without leaving either the proximal or distal side of the vessel patulous, thus securing all the advantages to be gained by ligating the vertebral and thyroid axes separately.

HAMILTON ON THE TREATMENT OF FRACTURES OF THE FEMUR BY IMMOVABLE APPARATUS.—In the *New York Med. Journal* for August, Dr. Frank H. Hamilton says: While I recognise the convenience and utility of plaster of Paris, and of other immovable forms of dressings, in the treatment of certain fractures, it has not proved satisfactory, under my observation, when applied in the treatment of fractures of the femur; and especially when applied immediately after the occurrence of the fracture—my own method of treating these fractures, without perineal bands, with side-splints, adhesive-plaster extension, pulley and weight, having given better results (with no accidents) in the adult. In the case of children, my double thigh-splint has also given better results than has plaster of Paris. These methods are far in advance of the double-inclined planes, and of Desault's, Boyer's, Hagedorn's, Gibson's, and other long splints. They avoid all danger of ligation and strangulation of structures; there is no perineal band to cause ulceration; extension is made by a method which equally—when properly applied—shuns the danger of ulceration about the heel, an accident common with the old gaiter; the patients are comfortable; the limbs are seldom united with deformity; and the average shortening is less than with any other method yet devised. The fact that a man walks without a halt is no evidence that there is no shortening of the limb. In this regard patients are very unequal; one, having a shortening of only half or three-quarters of an inch, will limp perceptibly; while another, with a shortening of one inch or even one inch and a half, may not limp at all. This has been observed repeatedly. Nor is it any evidence that the limb is not shortened because, while lying in bed, the heel of the broken limb can be brought down to the level of the other. By pitching the pelvis, the spine remaining erect, the heel may be made to descend, in most persons, two inches or more. Measurements made from the symphysis pubis, or from the round end of the anterior superior spinous process, are unreliable. The patient should repose upon his back, upon an even surface, with his lower extremities as nearly as possible in a line with the axis of his body, the two wings of the pelvis being in the same horizontal (transverse) line. A flexible, graduated tape-line is to be preferred to the steel tape-measure. The foot being steadied by an assistant, the surgeon should put his thumb-nail against the line where it joins the ring, and push his nail into the skin just below the anterior superior spinous process of the ilium, pressing firmly up and back, the back of his nail resting upon the skin. In this he obtains a fixed point, and he can obtain an exactly corresponding point upon the

opposite side. Below, the measurement may be made from either malleolus, but the outer has the most defined extremity, and is generally preferred. In most cases, for some months after the close of the treatment there is some œdema about the ankle, which renders it necessary to use great care in determining the point of the malleolus. The thumb-nail of the opposite hand may be used for this purpose, resting vertically upon the skin (flat against the lower end of the malleolus). There are a few sources of error which cannot be avoided. Occasionally, but very rarely indeed, the malleoli of the two limbs are of unequal length; and, in a few very rare cases, one limb is congenitally, or from defective growth, shorter than the other.

HAHN ON DRAINAGE OF THE ABDOMINAL CAVITY.—In no. 38 of the *Berliner Klinische Wochenschrift* (September 21, 1874), Dr. Eugene Hahn, of Berlin, communicates a case of ovariectomy in which he put in practice the intraperitoneal injections recommended by Peaslee, and the drainage of the abdominal cavity, recommended by Marion Sims in 1873. Sims shows that twenty-four of the thirty-eight fatal cases amongst Spencer Wells's operations, died from septicæmia (Beigel's translation.) Nussbaum says that his twenty-eight deaths after ovariectomy all resulted from the same cause. He thinks that twenty-three of them might have been saved by the use of the drainage-tube. Spiegelberg, in his pamphlet on the diagnosis of cystic myomata of the uterus, says that eight out of fourteen fatal cases were so from septicæmia, and might have been saved by drainage and the use of disinfectants. This treatment is applicable to many other cases than ovariectomy; in fact, to almost all in which the abdominal cavity is laid open; such, for example, as the operation for strangulated umbilical hernia. The subject of the ovariectomy was a midwife, who had noticed the tumour about two and a quarter years before. It was then of the size of a hen's egg, and was first noticed in the left side. After the birth of her fourth child (November, 1873), it enlarged with great rapidity. In April, 1874, about three gallons of colloid brownish fluid were removed by tapping. Some small cysts could be felt through the abdominal walls. Three months afterwards the tumour was as large as ever. Ovariectomy was therefore resolved on, and carried out in a private house. The abdomen then measured nearly forty-eight inches. An incision of about six and a half-inches long was made in the linea alba, and through this the tumour was removed. The right ovary proved to be healthy. As there were numerous adhesions, Dr. Hahn resolved on drainage, and passed the index and middle fingers of his left hand through the wound behind the uterus to the deepest part of Douglas's pouch, and introduced the corresponding fingers of his right hand *per vaginam*, so as to meet them. A curved trocar and cannula were then passed, the fingers guiding them, through the pouch of Douglas into the vagina, and the trocar withdrawn. About 2 feet of drainage-tube, $\frac{3}{4}$ th of an inch in diameter, with numerous perforations, were passed through the cannula. Through this tube, the upper end of which was secured at the lower edge of the incision, a solution of carbolic-acid (1 to 1,000) was injected, till the fluid returned colourless. In the first four hours, nearly $2\frac{1}{2}$ pints of fluid escaped from this tube. The carbolised injections were repeated several times daily. On the fourth day, in

the absence of discharge, and all injected fluids returning colourless, the drainage-tube was withdrawn, but a silver wire was left in its place, as a means of re-introducing it if required. On the eighth day, even this was withdrawn. On the next day after the operation her pulse was 84, and her temperature only 100.8° Fahr., in the evening pulse 92, temperature 100.4° ; whilst next day the temperature was normal, and the pulse did not exceed 80 after this date. The patient was fed for the first two days by clysters of two tablespoonfuls of brandy, with soup and eggs, every three hours. Thirst was relieved by ice. The sutures were removed on the fourth day; the clamp on the twelfth. The bowels acted on the seventh day after medicine given for that purpose, and after this she took solid food. The catamenia followed on the fifteenth day, and she returned home in good health on the twenty-fifth day.

W. BATHURST WOODMAN, M.D.

KAPTEYN ON A RARE FORM OF HERNIAL STRANGULATION.—In the *Nederlandsch Tijdschrift voor Geneeskunde*, no. 38 for 1874, Dr. H. P. Kapteyn describes a rare form of strangulation occurring in a case of scrotal hernia on the right side. The patient, a robust and well nourished peasant, had had the hernia for fifteen years; he had worn a truss, but the hernia sometimes escaped; it was, however, readily reduced.

On July 7 the bowel came down while he was at stool. A medical man was called in, and tried the taxis in vain; another, who was called in consultation on the 8th, injected morphia subcutaneously, but still reduction was impossible. Dr. Kapteyn was now called in, thirty-one hours after the accident, and found the hernia occupying the scrotum, which was of the size and shape of two fists. He proceeded at once to perform herniotomy. On opening what was apparently the hernial sac, he was surprised at not seeing a drop of fluid escape. The incision brought into view a bluish opaque mass, which, by the sight and touch was recognised as omentum. On examination with the finger, a narrowing was found at the external ring; this was enlarged sufficiently to enable the finger to pass into the abdominal cavity. He now endeavoured to reduce the intestine, but could not do so, although the inguinal canal was sufficiently large. Believing that there must be another stricture, he introduced his finger into the opening in the sac, and found that the gut was strangulated by a firm constriction with a sharp circular edge, at the lower part of the scrotum, close to the testis. Guided by his finger, the intestine being carefully held aside, Dr. Kapteyn succeeded in dividing the stricture in three places without injuring the gut. This proceeding was followed by the escape of some dark red turbid bloody fluid; and the hernia was readily reduced. The omentum was extensively adherent to the sac, and was left. The healing of the wound was retarded for some days by sloughing of the omentum; the patient had quite recovered seven weeks after the accident.

Dr. Kapteyn says that he has not been able to meet with similar cases in literature; but, while in London in 1862, he saw Mr. John Couper operate under similar circumstances. A. HENRY, M.D.

SYPHILOGRAPHY.

PROFETA AND PARONA ON TREATING VENEREAL SORES WITH IODOFORM.—Profeta (*Annales de Dermatologie et de Syphilographie*, tom. v. 1874) first alludes to the accounts of the value of iodoform when applied to ulcerating surfaces of all kinds, by several French and Italian surgeons, and then relates thirteen cases in which it was employed. Two were ulcerating hard sores, and ten non-infecting sores, some of which were phagedenic. In none did any mishap arise; cicatrisation proceeded steadily in all, and when the iodoform was applied to recent non-infecting sores, it healed them with surprising rapidity. The wounds were washed twice daily with solution of iodoform (iodoform, one part; alcohol, five parts; glycerine, fifteen parts) and then liberally sprinkled with the dry powder.

Two inconveniences attend the use of iodoform; its high price, fifteen grains costing one franc at Palermo [5s. 8d. per oz. wholesale in England, *Rep.*], and its disagreeable odour; the latter is so peculiar and penetrating that it renders the patient unfit for society while it is employed. The first case narrated was one of obstinate creeping sore following virulent bubo, which continued two years, and resisted a multitude of caustic, alkaline, and other applications, attaining in January, 1874, a circular shape with a diameter of two inches and three-quarters. When iodoform had been used eight days the wound was a simple granulating surface, and in twenty-four days was soundly healed. The application of the powder is rarely painful, and at once subdues the gnawing pain of seriginous sores, so that the patient tolerates the temporary smarting that sometimes attends the application.

Jullien (*Doyon's Annales*, tom. v. p. 461) describes the experiment of Parona of Novara, with iodoform applied to painful rhagades at the anus.

Parona found that the most effective mode of applying it was as an ointment (one part of iodoform to two parts of lard) spread on lint and inserted three times daily. The pain, especially that during defæcation, is assuaged at once, spasm subsides, and cicatrisation is rapid.

[The reporter has during the last twelve months employed iodoform extensively at the University College and Lock hospitals, as well as in private practice. His experience coincides in the main with that of Profeta and Parona. The reporter has employed iodoform hitherto only as a dry powder, but for seriginous sores of all kinds, as well as for spreading chancres. The iodoform appears to irritate suppurating wounds where there is no specific contamination. For example, iodoform was used in a case where the prepuce had been

circumcised, in order to get at the chancres underneath. Iodoform was at once applied to the chancres, and, as soon as suppuration began along the circumcision-wound, to that also. But the patient complained much of the pain when the inflamed surface was so treated, while none was felt at the chancres, which, moreover, did not inoculate the circumcision-wound. One of the reporter's cases was even better testimony than that of Profeta. The patient, a gentleman, had suffered from seriginous chancre of the foreskin for twelve months, by which a circular ulcer had destroyed a considerable part of the sheath and all the prepuce but a nodule of cedematous tissue connected with the frænum, and was invading the glans. Nitric acid, acid nitrate of mercury, sulphuric acid paste, and the actual cautery, were all freely employed on several occasions, under chloroform. The patient took mercuric vapour-baths also for a considerable time, sufficiently often to maintain spunginess of the gums and foetid breath. No further effect than temporary arrest of the phagedenic action and its attending pain followed each cauterisation. Iodide of starch was then regularly applied. This checked the eroding action, and subdued the pain, but did not produce granulation; and, after a fortnight's trial, it was replaced by iodoform. Then healing began in three days, and continued rapidly without a check, until in a fortnight a sound cicatrix had replaced the angry ulcerating surface. The patient has remained perfectly well to the present time, eleven months.—*Rep.*]

OPHTHALMOLOGY AND OTOTOLOGY.

BURNETT ON A CASE OF MOVABLE EXUDATION IN THE TYMPANIC CAVITY.—Dr. Charles H. Burnett describes, in the *Medical Times and Gazette* for October 17, 1874, one of those not uncommon cases where a movable exudation in the tympanic cavity was attended with variable hearing. The patient complained of deafness on account of having 'a drop in his ear,' the deafness depending on the position of the head, being entirely absent when he was in a supine position in bed, but returning on assuming the erect position or inclining the head a little forwards. Dr. Burnett, believing that 'the drop' was the perception by the patient of the motions of the fluid, causing a variability of hearing according as the position of the head caused a gravitation of the fluid into portions of the tympanic cavity remote from or contiguous to the sound-conducting apparatus or the fenestra, performed paracentesis of the membrane, and forced the fluid from the cavity into the external meatus

by a current of air from Politzer's bag with the happiest results. The use of Valsalva's method for forty-eight hours afterwards completed the cure, and the hearing remained normal. [Would the use of one of Weber-Liel's elastic tympanic catheters not have done equally well, without subjecting the patient to the risk that paracentesis entails?—*Ref.*]

VOLTOLINI ON THE GALVANO-CAUSTIC BATTERY.—R. Voltolini, in the *Monatsschrift für Ohrenheilkunde* for August, describes his small portable galvano-caustic battery, which he recommends for use in aural surgery. He prefers this method for perforating the membrana tympani to all others, as by it he can make instantaneously an opening of the desired size, which remains open and free, does not bleed, and allows the introduction of the cannula without difficulty. He uses the same cautery for the removal of the smallest polypi, or the remnants of larger ones, which have been partially extirpated by a galvano-caustic cutting snare, which he has made for the purpose, similar to the Wilde's snare, but with some improvements, which he thinks make it more easy of application. He also, in another paper in the same journal, describes the application of the galvanic cautery to the burning of foreign bodies in the internal auditory meatus, which cannot be removed in the ordinary way.

WEBER-LIEL ON TENOTOMY OF THE TENSOR TYMPANI.—Weber-Liel gives, in the *Berliner Klinische Wochenschrift* for September 21, the results of his further experience of the operation. He says that he is convinced that many cases of progressive deafness, accompanied by tinnitus, are only to be benefited by this tenotomy, but warns the surgeon that it is not to be looked upon as a remedy against certain diseased processes, but against certain conditions common to different forms of ear-affection, viz., increased tympanic tension and heightened intralabyrinthine pressure. From 225 operations he concludes that tenotomy of the tensor tympani may, where every other means has been found useless, relieve vertigo, abolish or greatly reduce tinnitus, and improve the power of hearing; but relapses in old standing cases are not uncommon, on account of the other secondary changes which have occurred in the middle or internal ears. Where the operation was looked upon merely as a step to further treatment of the tube and cavity, the relapses were much more seldom, and it is in this light that Weber-Liel wishes it to be considered. W. LAIDLAW PURVES.

REVIEWS.

The Pathological Anatomy of the Nervous Centres. By EDWARD LONG FOX, M.D. London: 1874, pp. 401.

So far as we are aware, this volume of Lectures is the only work which presents in a readable and convenient form for the use of students and practitioners, the pathological information having reference to the Brain and Spinal Cord, otherwise lying scattered in publications of various kinds, necessarily inaccessible to many. That this information is collected by one who has himself added to the common stock of scientific knowledge in this department, offers at once a guarantee of the exactitude and value of this treatise. The vast extent of the subject may, as Dr. Fox urges, well plead in extenuation of any deficiencies or defects in its execution; while he observes with much truth 'that in this department, as in so many others, we are indeed but as children picking up pebbles on the shore of the ocean of truth.'

Among the introductory observations with which the author prefaces the body of his work is the following, which we think worthy of note. 'One consideration is the debt we owe to pathological anatomy for our knowledge of the physiology of the brain and spinal cord. Without for a moment undervaluing the experimental researches of Brown-Séquard on the spinal cord, or the still more important contributions to the physiology of the cerebral convolutions by Hitzig and Ferrier, it must be confessed that nearly all we know of the real functions of the various organs of the encephalon and spinal cord, has been drawn from observations of the effects of lesions. Disease is nature's most delicate experiment; and what knowledge we have of the seat of language in the brain, of the functions of the corpora striata and optic thalami, of the regions specially associated with sensation, with motion, and with thought, is mainly gathered from this, her constant mode of teaching.' The supreme illustration of this proposition needs to be sought for no further than in the pathological investigations of Dr. Hughlings Jackson; but collateral support may be found on all sides.

For convenience of study, the author has treated his subject in two divisions, viz., first, the pathological anatomy of the brain and spinal cord, including, 1, congenital abnormalities of the cerebro-spinal centres; 2, abnormalities of the vascular system; 3, inflammation; 4, degeneration; 5, tumours; and, secondly, the mode in which these pathological results are grouped in certain conditions which symptomatically have been given special names, as mania, melancholia, etc. Dr. Fox remarks that no division can be perfect; thus, 'it is not logical, in a pathological sense, to divide degeneration from inflammation on the one hand, and from some tumours on the other. It is not only probable, it is certain, that some forms of degeneration own an inflammatory origin. It

would have been possible to make the division according to the anatomical constituents, and to have taken the organ to pieces, as it were, and then to have considered in detail the abnormalities of the vessels, of the connective tissue, and of the nerve-cells and nerve-tubes, that go to make up the structure of the nervous system. But a plan of this kind would necessarily have led to much tautology.' The author has, however, appended a sketch of a classification, made upon an anatomical basis, which is not without its value for the sake of comparison.

As it would obviously be beyond our space to attempt an analysis of the entire work, we select for our present purpose a chapter from each of the two principal divisions of the work, viz. (1), the pathological anatomy; and (2) the grouping of the pathological results.

Under the first division, we take the subject of Inflammation;—co-extensive, it might almost be said, with the whole range of lesions of the brain or spinal cord. The pathological changes induced by this condition are followed through the several structures constituting the nervous centres. In treating of inflammation of the dura mater, Dr. Fox traces the formation of bony deposits to inflammation thus. 'In the non-purulent form, the new formation, the result of the inflammation, becomes very quickly the seat of vessels, and is composed of several layers; those nearest the dura mater being composed of compact lustrous connective-tissue fibres, almost as dense as the dura mater itself; whilst the layer further removed from the dura mater is rich in cells, with small and narrow vessels; and the layer nearest the arachnoid, often firmly uniting the arachnoid to the dura mater, is remarkable for very large capillaries. It is from rupture of these vessels that hæmorrhage occurs; the blood being not unfrequently locked up in the lacunæ of false membrane poured out beneath the dura mater. From further alteration of these inflammatory products result the laminae of bone that are sometimes met with on the visceral surface of the cranial dura mater, especially in the falx cerebri and falx cerebelli, and still more frequently on the dura mater spinalis. So far as I know, this ossification is never preceded by the formation of cartilage. The bone, true bone as it is, is formed from fibrous tissue, this fibrous tissue being a further development of the inflammatory exudate from the vessels of the dura mater.' (p. 59.)

Inflammation of the arachnoid, Dr. Fox points out, can scarcely be separated from that of the adjacent structures; and although, therefore, these are treated of conjointly, the author does not omit a notice of the 'various degrees of thickening of arachnoid, with sometimes deposit of lymph on the upper or under surface of its visceral layer, if not of both. The arachnoid may appear milky from two causes; either from the presence beneath it of slightly turbid fluid, such as the cerebro-spinal fluid in not quite a normal condition, or from the faintest commencement of thickening of the membrane itself.' Then follows a description of the various morbid conditions in which thickening of the arachnoid is met with; e.g. granular kidney, senile dementia, heart-disease, cancer, cerebro-spinal meningitis, tubercle, and disease or injuries of the dura mater.

The impossibility of separating the inflammatory condition of the arachnoid from that of the pia mater is shown by the occurrence of the deposition

of lymph or pus on its surface. 'This is especially seen to be the case in tuberculous and in cerebro-spinal meningitis. In the former case, indeed, the arachnoid, when inflamed, seems only so in direct ratio and extent with the pia mater, and the pia mater may be affected whilst the arachnoid is almost wholly or wholly free.' . . . 'Although it is difficult to separate the abnormalities of the pia mater from those of the arachnoid, yet it is generally easy to speak with certainty of these abnormalities having their origin in the pia mater.' (p. 63.)

Dr. Fox observes that whether meningitis ever occurs independently of syphilis, rheumatism, alcoholic poisoning, tubercle, anæmia, or mechanical irritations, is, at least, an open question. The constitutional origin of meningitis is often very far from clearly made out. We remember to have seen an instance in which, after amputation of a lower extremity, without any untoward symptom, the patient became listless and apathetic, and in a few days died, without any obvious reason. On *post mortem* examination, the whole cavity of the cerebral arachnoid was found lined with a thick layer of yellow lymph. Of course there might have existed one or other of the constitutional conditions above referred to; but, owing to the obscurity of the symptoms, there was no indication leading up to either.

The anatomical description of the membrane in different degrees of inflammation is fully and well given by Dr. Fox. The condition of the brain and spinal cord, the author adds, varies in meningitis. 'Sometimes the organs are healthy, or nearly so; in other cases the external cortical layer is found adherent to the pia mater, and is detached with it. In others, again, there is simply hyperæmia, or more or less induration; but softening is more common, varying much in degree, but not unusually very general.' Dr. Fox states that softening of the subjacent nerve-substance is less frequent in the spinal cord than in the brain. In this opinion we concur, as we have often failed to meet with softening in cords from cases of spinal meningitis.

Dr. Fox does not admit a difference between acute hydrocephalus and the condition of the ventricles in tuberculous meningitis. Acute hydrocephalus he holds to be generally tuberculous meningitis, with the lining membrane of the ventricles more implicated than is usually the case in ordinary meningitis of the base. A similar condition, he adds, may be found in chronic hydrocephalus, which is not usually an inflammatory affection; in general paralysis of the insane, in chronic mania, and sometimes also in melancholia. External hydrocephalus the author rightly disposes of as not existing otherwise than in atrophy of the brain, with substitution of cerebro-spinal fluid for the shrunken convolutions.

Encephalitis, with or without cerebral abscess and Myelitis, comes next under consideration in this chapter, and is described at considerable length. This last named lesion is one not always easy to distinguish from other or even from *post mortem* changes. That softening is not simply a result of meningitis may safely be affirmed, since it is to be found without this antecedent condition. That the account given by Dr. Fox of this lesion is correct, there can scarcely be a doubt on the minds of those who have had experience in this portion of pathological histology. The description is illustrated by two well executed and truthful lithographic representations.

Our space compels us to pass over without detailed

consideration the two following chapters on Degenerations and on Tumours, both of which are as fully and elaborately handled as those which precede them, and of which we have presented an imperfect outline.

The second division of Dr. Fox's treatise, as already stated, is occupied with the consideration of pathological results grouped under certain recognised names. In order to exhibit the author's mode of discussing these, we take for our illustration Facial Paralysis. Dr. Fox, with reference to the pathological history of this affection, observes that in our ordinary way of speaking of it we include a great variety of morbid conditions. In order to understand these we are thus reminded of the origin and course of this nerve. 'Here again we owe our thanks to Stilling and Lockhart Clarke for the discovery of the relations of the nucleus of the facial with the nuclei of other nerves. The hypoglossal, the vagus, the spinal accessory (in part at least), the facial, and the fifth, all have nuclei closely associated with each other in the lower part of the medulla oblongata. Besides these, close to the olivary body, the sixth nerve arises from the same nucleus as the facial.' Dr. Fox further, in connection with this topic, points to the decussation of fibres of the facial across the raphe, high up in the medulla; and then follows the course of the nerve to its exit from the skull and its ultimate distribution. The division of lesions of the facial nerve into those inside, and those outside the stylomastoid foramen, is justly regarded by the author as inferior to that by M. Jaccoud, into cerebral and peripheral; the peripheral being again divided into basilar, interstitial, and superficial.

'Central lesions,' Dr. Fox adds, 'confined to the nuclei of this nerve, are extremely rare. Hæmorrhage into that portion of the medulla would very rapidly prove fatal. Still, judging by the analogy of glosso-pharyngeal paralysis, a lesion that implicates these nuclei may exist.'

Dr. Hughlings Jackson's explanation of cross paralysis is here quoted by the author. The facial nerve being paralysed on one side, the limbs on the other—'Since the nerve-fibres for the limbs cross below the pyramids, those of the left arm and leg will pass on the right side of the pons, on their way to the higher parts of the motor tracts. But the facial nerve of the right side runs through the lower part of the right side of the pons to its nucleus, on the floor of the right ventricle. Hence a clot, which damages the right facial nerve, damages also the motor fibres which have come over from the left arm and leg.' In this complete manner Dr. Fox traces the various lesions of the brain and medulla, so far as known to be associated with affection of the facial nerve; observing, 'The lesions in the brain itself affecting any portion of the portio dura directly must be in the pons, the crura cerebri, the optic thalami, or the corpora striata. But any lesion of the cerebral hemispheres that causes either pressure or irritation of the corpora striata may indirectly induce slight paralysis of some fibres of the portio dura.' The lesions of the facial nerve after it has emerged from the stylo-mastoid foramen are next described; but here it is unnecessary to follow our author. Nor for the purpose in hand is it requisite to go over the subsequent sections of this work.

We trust that we have in the preceding extracts and observations sufficiently set forth its character. To

have attempted an exhaustive analysis of such a series of anatomical demonstrations as is therein contained, would inevitably have involved some degree of injustice to the author—and still more to the readers. We should fail in our duty to the latter if we did not endeavour to impress upon them that this work, for the present at least, stands alone in scope, and could not easily be surpassed in execution. The bibliography that is appended to each section would alone render it a book to be consulted by all who are interested in the prosecution of pathological science.

W. B. KESTEVEN.

The Period of Infection in Epidemic Disease. By WILLIAM SQUIRE, M.D., M.R.C.P. J. and A. Churchill. London: 1874.

We cannot say, after a careful perusal of Dr. Squire's essay, that he has added much to our knowledge of the duration of the incubation-period in epidemic disease. Indeed, of the majority of epidemic diseases, such as typhus fever, enteric fever, small-pox and cholera, nothing of any importance is to be found on the subject of incubation; and what there is in reference to rubeola, measles, and scarlatina is rather confirmatory than new.

Of the duration of the period of infection in epidemic diseases, by far the most important question in reference to the spread of these diseases, the information afforded is not only very scanty, but in our opinion very incorrect. Dr. Squire divides infectious diseases into two classes; one consisting of diseases which have a long incubation-period, such as small-pox, typhus fever, and enteric fever; another comprehending diseases which have a short incubation-period, such as erysipelas, scarlatina, and cholera. Speaking of the first class, he says, 'Infection continues with great intensity during the earlier convalescence. In small-pox, measles, mumps, and varicella, for a fortnight after the eruption the greatest care is requisite to guard against their spread; but many instances point to the infection of those diseases of slow ingress disappearing in a comparatively short time afterwards, so that three weeks may often suffice to terminate the persistence of personal infection; this, in small-pox, corresponding to the disappearance of the last pustular crusts.' Now, as regards intensity of poison in typhus fever, this is simply, and without any qualification, the very reverse of fact. At no period of this disease do we think that the poison admits of being described as 'intense,' much less the period of convalescence. There is, we believe, excluding the infectious bowel-diseases, no disease whose poison can be so rapidly and completely destroyed, by the simple means of abundant supplies of fresh air, as typhus; and no infectious disease, individual cases of which may be attended upon with so much impunity. Attendants upon single cases of this fever more rarely contract it than under the same conditions they contract small-pox, scarlatina, or measles. Even when the poison of typhus is concentrated, as in the wards of fever-hospitals, it is rare for nurses, exposed as they are for twelve hours daily to the exhalations of twenty or thirty fever-patients, to succumb to the disease until after an exposure of from six weeks to two months. The present writer was exposed to the poison of typhus for eighteen months before he contracted it; and he has at present under his care a patient who resisted typhus poison in a highly concentrated form for ten months. Now if the infecting cause were 'intense,' the impunity

described would not have had place; and it cannot be said of small-pox, scarlatina, or measles that similar exposure has been attended with a like immunity. As regards the persistence of infection during the earlier convalescence of typhus, we dare say that of no infectious disease may it be affirmed with so much certainty as of typhus that, as soon as fever has gone and the appetite has returned, the patient, having been well washed and supplied with clean clothing, may be safely permitted to mix in society. There are here no crusts as in small-pox, no scales as in scarlatina, and no morbid intestinal products as in enteric fever. The proof of all this is simply the fact that, during early convalescence, typhus fever patients have again and again been sent from fever-hospitals to convalescent homes without infecting the other patients. To our own certain knowledge, early typhus convalescents have frequently, and in considerable numbers, freely mingled with enteric fever patients and with scarlatina patients without communicating the disease in a single instance. With these facts before us, we cannot help dissenting from Dr. Squire's statement on page 45, that typhus fever is the 'most infectious of diseases;' nor can we think with him that Dr. Murchison's statement that typhus convalescents do not spread typhus, requires any correction. But one statement in the quotation we have made from Dr. Squire's paper appears to us to require very serious correction, inasmuch as, if acted upon, it is reasonable, or at least wise to assume, that it would contribute in no small degree to the spread of the most infectious and most loathsome disease known, to wit, small-pox. Dr. Squire in effect says that personal infection may often disappear in small-pox in three weeks, and that this time corresponds with the falling off of the crusts! This surely is dangerous doctrine. Would Dr. Squire recommend the mixing in society of desquamating scarlatina patients? And yet, to let loose upon a community small-pox patients, as soon as their crusts had fallen off, would be about as safe as to let loose scarlatina patients whilst desquamation was actively going on. Dr. Squire appears either to ignore or to have forgotten the desquamation or desiccation which follows the fall of small-pox crusts; and that *even in discrete variola the crusts* often adhere until the twentieth day on the face, and of course on the rest of the body a little later. 'There remains in their place,' says Trousseau, 'not a depression, but a projection of a violet-red colour, deeper in shade if the individual be exposed to cold. On this projection a small scale of epidermis is seen to form; this, after some days, becomes separated and is replaced by a thinner one, which in its turn falls off, and gives place to another; and so on in succession during ten, fifteen, twenty, or even thirty days.'

Now, without maintaining that the poison of small-pox is retained in these scales and may communicate the disease, this much is clear, that in the mildest form of variola, morbid products may continue to be thrown off the body, according to Trousseau, for nearly two months; and surely no sane man, with this fact before his eyes, would say that personal infection in small-pox (as far as appears from the paper, too, any kind of small-pox), will have ceased to exist in three weeks. We fear that the fall of the crusts is too often taken as the indication of the time when a patient may safely mix with his neighbours; and that in this way the disease is to no small extent propagated.

There are several curious statements in this monograph; for instance, the doctrine that 'measles is more common in winter and spring, because the pulmonary mucous membrane is then more susceptible'; and, that 'scarlet fever continues to be infectious long after all remnants of local morbid action have been removed.' One more is so characteristic of Dr. Squire's method of arriving at general conclusions, that we quote it entire. 'A midshipman of H.M.S. *Shannon* was put on the sick list 2nd May, 1857, for a wound of the foot; on the 7th of May he was attacked with febrile symptoms which proved to be those of scarlatina. The ship anchored in Simons Bay, Cape of Good Hope, on the same day, not having communicated with the shore, or with any vessel since leaving England, on the 25th of February. The *Shannon* was at Portsmouth in February, 1857, when some children near this young man's father's house at Southsea had scarlatina. Here, although the infection had lain dormant for nine weeks, it becomes operative in the usual period of incubation, five days after a susceptibility is induced by the wound.'

Now, we venture to say that there is not a particle of evidence in the extract which we have made to justify the conclusion that the midshipman referred to caught his fever, *if fever he ever had*, at Portsmouth. The evidence consists of a series of pure assumptions; to wit, first, that the infection had lain dormant for nine weeks; second, that the usual period of incubation in scarlatina is five days; and third, that susceptibility to scarlatina is produced by wounds. As regards the incubation period of scarlatina, the facts on the subject are unsatisfactory in the extreme. Aitken fixes this period at from eight to nine days. Trousseau says, 'This period cannot be rigorously determined in the present state of our knowledge.' (*Clinique Médicale*, tom. i. p. 100.) Dr. Gee says of it, that it 'partakes of that irregularity which attends most of the points which go to make up the history of scarlet fever.' ('*Reynolds*,' vol. i. p. 153).

Barthez and Rilliet say 'The facts in our possession cannot give an exact solution, for it is impossible for us to determine with certainty the moment of infection.' (*Maladies des Enfants*, tom. iii. p. 206.) Vogel says, 'This period of time is not the same in all children; in most cases it lasts from six to eight days; important deviations from this ought to be received with great caution, inasmuch as during an epidemic it is rarely possible to fix the day of infection with absolute certainty.' (*Lehrbuch der Kinderkrankheiten*, p. 397.) As regards our author's third assumption, where, we ask, is the evidence upon which it is supported? and as regards the first assumption, why are we to believe that scarlatinal poison was absorbed at all, and where is the evidence proving communication between the sick house and the healthy house?

To ask one's assent to conclusions founded upon evidence of this sort is an insult to the human understanding.

The really valuable part of the paper is that which gives the cases illustrative of the duration of the incubation-period in measles and scarlatina; and of these, all that it is necessary to say is that they confirm previous observations.

ALEX. COLLIE, M.D.

MISCELLANY.

PROSCRIPTIONS OF MEDICAL MEN.—The German medical journals report, that the *Obzor*, a newspaper published at Agram in Croatia, has since June adopted the very singular and unnecessary course of adding to each announcement of a death the name of the medical practitioner who attended the deceased.

DIPSOMANIA.—Contrary to the usual opinion, which attributes to the inhabitants of the British Isles the greatest average of drunkenness, the *Ausland* states that this vice flourishes to the greatest extent in the United States and in Russia. The asylum provided by the State of New York to receive confirmed drunkards contains 800 inmates, who are classified as follows: 30 clergymen, 8 judges, 197 lawyers, 226 medical men, and 340 unclassified, but chiefly consisting of merchants, artisans, and business men.

SIR RANALD MARTIN.—By the death of Sir Ranald Martin, India loses one of her most valuable public servants. No one had done more to lay down the principles by which life and health may be preserved in that climate. As an early advocate of hill sanatoria, of improved barrack accommodation, of improved water-supply, and of army-sanitation, Sir Ranald Martin was able to lead the van in those great sanitary reforms which have been worth an army to this country, and have reduced the invaliding from India from its former excessive rates, to a rate not very greatly in excess of a European standard.

DESERTS AS HEALTH-RESORTS.—At a recent meeting of the Munich Academy of Science, Professor Zittel read a paper, detailing the results of observations made by him with regard to the air of the Lybian desert during the months of January, February, March and April, 1874, tending to prove that this desert contains a very much larger amount of ozone than that of the oases, or the Nile valley. The belief that the desert air is beneficial to invalids, especially those suffering from pulmonary complaints, is of ancient origin, and, in accordance with this idea, the Khan has recently decided to repair to Helnau, in the so-called Eastern, or Arabian, desert of Egypt.

THE OPIUM CROP.—This crop, according to the *Philadelphia Medical and Surgical Reporter*, now averages from 4,000 to 6,000 baskets or cases. Of this quantity the United States require above 2,000 cases. The price has risen lately, averaging 17. per pound. Fifteen years ago it averaged 15s. per pound. Owing to the late high prices, some persons at Smyrna have, during the last two years, adulterated the pure drug by mixing it with spurious matter, and passing it off as first quality. They succeeded in selling about 300 cases during the last two years; but, as the fraud has been discovered, the consequence has been that purchasers have been very careful from whom they obtain this drug. The crop for 1874, which is collected in May and June, has suffered considerably from the late severe frosts; consequently a short yield will also increase the value. In 1873 the stock existing in Smyrna was 1,500 baskets; in London, 700; and in the United States 600 baskets.

FOREIGN BODIES IN THE DIGESTIVE CANAL.—The incident of the *homme à la fourchette*, the man who swallowed a fork in Paris in April last, has inspired Dr. Mignon with the idea of collecting all records of similar cases. He has been able to find details of one hundred and sixty-three, and it would be difficult to imagine anything more astonishing than the catalogue (given in the *Union Médicale* for November 3) of the objects swallowed by either veritable lunatics, or what may be termed sane idiots. Amongst the very indigestible and uncomfortable items catalogued we find fifteen gold medals, hair rings innumerable, 175 francs, a shoe buckle, nine inches of a sword blade, very sharp scissors, eighty pins, a baby's bottle, the castor of a night-stool, an entire set of dominos (the size of which however is not stated), one hundred *louis d'or*, a flute four

inches long, a glass phial, thirty-five knives, a clay pipe, from fourteen to fifteen hundred pins, a bar of lead weighing a pound, a whetstone, and (in three instances) a table fork. But the most extraordinary of all these cases occurred in the instance of a convict who died at Brést in 1773, and on whose body a necropsy was performed. The stomach was completely displaced and occupied the left hypochondrium, the lumbar and iliac regions of the one side extending into the pelvis nearly as far as the foramen ovale; it contained fifty-two different objects, weighing altogether 1 lb. 10 ozs. Amongst them was a part of the hoop of a barrel, nineteen inches long and one wide. M. Mignon has classified these 163 cases into three categories. 1. Foreign bodies which passed through the whole extent of the digestive canal with scarcely any injurious results. 2. Foreign bodies which have passed through the whole extent of the digestive track, with more or less serious results, but ultimate recovery. 3. Foreign bodies, which have passed through the whole digestive track, causing serious disturbance and fatal results. 4. Cases in which the foreign body has not been passed. 5. Cases in which operations have been performed. It is a remarkable fact that the cases of death caused by the presence of foreign bodies in the digestive tubes are less numerous than might be expected. Out of the 163 cases, we only find ten deaths from this cause. To these must be added two deaths after operation, making altogether twelve, or 7.3 per cent. There appears, therefore, to be no great cause for the surgeon to be over anxious in these cases, but to remember that unless there should either be some complications in the general health or some special indication, it will be as well for him not to interfere, and above all things not to perform gastrotomy, save as a last resource. Of this last operation M. Mignon relates five cases; amongst them being those which Mr. Neal, in 1855, and Mr. Bell, in 1859, thought themselves obliged to perform, the one in order to extract a bar of lead ten inches long, and weighing a pound, the other to do the same with a bar of lead, nearly twelve inches long, and weighing more than nine ounces. In both these cases the symptoms were very serious, comprising violent pains in the stomach, twitchings along the vertebral column, sickness and general prostration. The foreign bodies could not be felt through the abdominal walls, but the surgeons decided on performing the operation, thinking that the sufferers had no chance of relief by expulsion *per anum*. The success of the operations was fortunately complete.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17s. 4d.; free by post, 19s. 6d.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & Co.'s London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre.—Leipzig: Mr. K. F. KOEHLER.—Florence: Mr. E. LOESCHER.—Brussels: Mr. C. MUQUARDT.

The First Volume, containing upwards of Two Thousand Articles abstracted and compiled by a staff of Fifty Hospital Surgeons and Physicians, is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for the year 1873 are also ready, price 1s. 6d. each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART.—Amsterdam: W. H. KIRBERGER.—Bombay: THACKER, VINING & Co.—Calcutta: THACKER, SPINK & Co.—Melbourne: GEORGE ROBERTSON.—Montreal: W. DAWSON & Co.—New York: G. PUTNAM'S SONS.—Paris: JOHN ARTHUR & Co., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, DECEMBER 9, 1874.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

BUCKNILL ON THE LAW OF MURDER, IN ITS MEDICAL ASPECTS.

Dr. Bucknill (at the Annual Conversazione at the West Riding Asylum) delivered an address on the law of murder, in its medical matters (*British Medical Journal*, November 28, 1874.)

A *résumé* of this address is almost impossible, as every word of it is so much to the point that it is worthy of being carefully studied not only by every alienist, but also by the profession and the public at large.

The materials collected by the Parliamentary Committee for a statute to amend the law of homicide, seem to contain the following matters of especial interest to members of our profession :—

1. The definition of murder and of manslaughter.
2. The difficulty of proving infanticide, and the proposed alteration of the law thereupon.
3. The responsibility of surgeons operating without consent.
4. The plea of insanity.

According to Mr. Fitzjames Stephen, Q.C., who, together with Baron Bramwell and Justice Blackburn, was examined by the committee, there appear to be three natural divisions of the subject of homicide.

1. (a) It is murder, if you intend to kill the person.

(b) It is murder, if you intend to do the person grievous bodily harm,

2. It is manslaughter, if you do not intend to do grievous but only ordinary bodily harm.

Dr. Bucknill says: This distinction between grievous bodily harm and ordinary bodily harm which is not grievous, is a question which is invariably left to the jury, and, as such, is one of common sense rather than of law, although it is obvious that it is also one in which common sense must frequently be in need of medical guidance.

3. The last kind of homicide is, when you do not take proper care or employ proper skill and cause death in that way.

It would appear that the old definition of murder, that it was killing with malice aforethought, is quite exploded and obsolete, so far as the forethinking or premeditation is concerned. The old terminology is now simply a handle for advocates, which they well know to be illegal, and a loophole for juries. Malice, or some other term implying bad intention, must be preserved; but the condition that it must be *pre-pense* or aforethought, already extinct in practice, ought also to be abolished, as misleading and mischievous in the phraseology of the law.

Constructive Malice.—In illustration of this point Dr. Bucknill quotes the case of the Fenians, who, intending to rescue Dasent and Kelly, fired shots at

the van in which they were being conveyed, and killed a policeman. The man Dasent was in one of the compartments of the van, and afterwards it was found that the shot had gone through that compartment and penetrated the wood and gone out at the other side, and if Dasent had been standing upright it would have gone into his head and killed him. There is no doubt that that would have been murder as the law stands; but it would have been difficult to persuade anyone that, in the popular sense of the word, the men had any malice towards the person killed, when they were risking their lives to rescue him. That is an instance of constructive malice which everyone would wish to preserve.

Killing in committing Felony is Murder.—Three boys were walking through the streets of Birmingham to pick pockets; an old gentleman, who was fat and weak, came walking along with a gold watch in his pocket. One of the boys gave him a slap to make him bend forward, and the poor old man did bend forward, and died by reason of that slap. As he bent forward, the boy pulled out the watch from his pocket and handed it to the second, and the second to the third. They were all tried and condemned to be hanged.

Murder without Intention to Kill.—This point is illustrated, says Dr. Bucknill, by Mr. Stephen by the Clerkenwell explosion case, in which a man named Barrett exploded a barrel of gunpowder against the wall of a prison, with the intention of making a breach in the wall through which the Fenian prisoner, Burke, might be rescued. The explosion killed a number of poor people outside the prison, against whom Barrett doubtless had no malice, and he was hanged for murder.

Year and Day Limit.—The rule of law is, that to constitute murder the death must have occurred within a year and a day of the act which caused it. Mr. Stephen says that this, in substance, is a rule of evidence, and a very rough kind of rule of evidence, adapted to an age when there was very little medical knowledge. Possibly this question is only likely to arise at rare intervals.

By a Drunken Man.—Mr. Stephen is asked, with reference to the insanity clauses of his bill, whether he would include delirium tremens in the diseases which would prevent a man from knowing the nature of an act, so as to render homicide not criminal. Dr. Bucknill remarks on this question, that, knowing somewhat more of delirium tremens than lawyers are supposed to do, we must allow that it is not a frequent cause of homicidal violence. But the delirium from drink, which commonly results in homicidal violence, is that which we recognise as *delirium à potu*, the really dangerous delirium from drink the lawyers do not appear to have recognised. Men who have suffered from blows or wounds on the head, or from sunstroke are, we know, peculiarly liable to this frantic kind of drunkenness, and often from small amounts of stimulants.

Murder without Injury to Person.—By this is meant such a case as the following. Suppose a man wants to murder his wife; and suppose that she is ill, and the doctor says to him, 'She is in a very critical state; she has gone to sleep, and, if she is suddenly disturbed, she will die, and you must keep her quiet.' He goes into the room, makes a noise, and wakes her up with a sudden start, and frightens her; and she does die according to his wish. It seems to Mr. Stephen that this act is as much murder as if he had cut her throat. It seems to Dr. Bucknill

that this was the weakest and most assailable point of Mr. Stephen's very able draft, and that it did more to prejudice the committee against the bill than anything else. It was carrying the idea of murder into the abstract, and would have been applicable to the case of a man breaking the heart of a girl, or bringing down the grey hairs of his father with sorrow to the grave.

Chloroform.—In reference to this, Mr. Stephen says, that he supposes that a *bonâ fide* operation upon a man when he was insensible, which caused his death, if done for the best, would not be now a criminal act.

If the man were conscious and sensible, and if people were to say, 'The best thing that can be done for that man, is to take his leg off,' and he says, 'I do not consent,' but nevertheless his leg is taken off and he dies, and the jury is of opinion that it is a beneficial operation—in such a case, Mr. Stephen says, he is sure he could not say off-hand whether that would be manslaughter or not.

Dr. Bucknill asks would it be a trespass to tie an artery, or to cut for strangulated hernia, which he has himself done under chloroform, notwithstanding the vehement refusal of the patient, *who was, however, not of sound mind.* (The italics are the reviewer's.) In answer to this, the writer of this *résumé* would suggest that the same rule would hold good as in the case of an unconscious patient.

Dr. Bucknill proceeds to relate another case. A man intending to commit suicide bought half an ounce of arsenic, as he supposed, and swallowed it, telling his wife what he had done. Medical aid was procured, and the supposed arsenic was forcibly removed by the stomach-pump; but the man died. On the inquest it was proved that the chemist, suspecting the intentions of his customer, had given him powdered gypsum instead of arsenic; and it was found that death had been caused by injury to the coats of the stomach produced by the tube of the pump.

Was the surgeon in this instance guilty of criminal homicide, or could the representatives of the dead man maintain an action of trespass?

It appears to the writer of this paper that, although the result may have been the same in both cases, the extent to which the surgeon was responsible was not the same.

The difference between the case of the patient dying from an operation, who protested against his leg being cut off, and the case of the suicidal one who died from the use of the stomach-pump, seems to lie in the objection made in each instance.

The patient objected in the first instance, because he wished to save his life; in the second, because he wished to lose it. Had the surgeon not used the stomach-pump in the second case, he would have been aiding and abetting the patient in his act of supposed suicide.

Infanticide.—The question, as discussed before the committee, divides itself into two parts: 1. The period at which an infant, being born or newly born, becomes a person, and taking its life becomes infanticide; 2. The condition, as to soundness or unsoundness, of the mind of a parturient woman.

The bill deals only with the first consideration; the importance of the continued connection with the body of the mother by means of the umbilical cord seems to be a most important point. In reference to this difficulty, Justice Blackburn says as follows. What I would do myself would be this: I would make it a substantive felony for the parent of a child,

either before, or at, or during, or immediately after the birth, to cause the child to be prevented from being born alive, or to die; when that was done intentionally, I would make it a substantive felony, to be punished severely. That would be met by the Infanticide Bill which I have had shown to me.

Dr. Bucknill says—The state of mind of puerperal women is dealt with by Mr. Stephen in a spirit of pitiful and indulgent humanity, which is not very common among criminal-law makers. Whether he goes too far or not, we mental physicians must leave to the more intimate knowledge of our obstetrical brethren. While, as men, we cannot fail to feel commiseration for the shame and terror of a parturient woman who is bringing forth a child without the sanction of the law, the church, or society; and, as physicians, we must recognise the profound nervous disturbance which the act of parturition very commonly occasions, we cannot shut our eyes to the fact that the destruction of a child by its parent is an act of deep moral depravity.

Dr. Bucknill goes on to say: If, however, I understand Mr. Stephen aright, his remarks do not apply to puerperal insanity strictly so called, but to the unhinged condition of mind, which is, with more or less truth, attributed to all puerperal women; and on this point, I think, we are in need of accurate medical data.

Short as this sketch of Dr. Bucknill's paper must necessarily be, it is hoped it may induce those who have not already studied it, to read it in full.

We trust that on some future occasion we shall welcome another paper on the plea of insanity, from the pen of our greatest English authority on psychological medicine. HENRY SUTHERLAND, M.D.

BRAUN-FERNWALD ON ENUCLEATION OF ENCYSTED UTERINE FIBROMA.

In the *Wiener Medicinische Wochenschrift* (September 26, and October 3 and 10, 1874) Professor C. Braun-Fernwald has published an account of several cases of uterine fibroma on which he has operated, and has given a concise history of the operation.

Interstitial fibroids of the uterus are not connected with the uterine walls by any firm union, but surrounded with a loose layer of cellular tissue, and are consequently capable of being shelled out of the capsule of the uterine parenchyma.

Velpeau recognised the possibility of enucleating fibroma; Amussat of Paris, in 1840, and Atlee of Philadelphia, in 1845, were, however, the first who carried it out with success.

Up to the time when the author first performed the operation, in July, 1873, there were known to him forty-six published cases of enucleation of large uterine fibroma, in thirty-eight of which recovery took place; in one, after induction of premature labour, in one before the birth of the child, in four a few days after the birth of the child, and in thirty-two at a time beyond the puerperal period. In ten cases the result was fatal. A short *résumé* of these cases is given, and the mode of extraction is mentioned in most instances.

Grimsdale (*Liverpool Medico-Chirurgical Journal*, January, 1857) after inducing abortion on account of hæmorrhage in the fourth month, removed a fibroma as large as a placenta from the posterior wall of the uterus. A pregnancy afterwards took place, and resulted in the delivery of a still-born child.

Yeld (*British Medical Journal*, January, 1871) extracted a dead foetus by the feet, and next removed, by a blunt hook, a fibroma nearly eight inches in circumference, before the expulsion of the placenta.

Senderling (*Philadelphia Medical and Surgical Reporter*, xx.) after the delivery of the child and placenta, on account of continued hæmorrhage, enucleated with his fingers a fibroid as large as an apple. The patient recovered.

Kiwisch (*Klinische Vorträge*, Band viii.) on account of continued hæmorrhage, cut off a sessile fibroid as large as a hen's egg, situated on the anterior wall, and enucleated it with his finger and scissors. Recovery followed.

Ramsay (*Edinburgh Medical Journal*, 1858) nearly succeeded on the fourth day after delivery in enucleating a sessile fibroma weighing two and a half pounds, and situated in the anterior wall. It was spontaneously thrown off on the sixteenth day; and the recovery followed.

Braxton Hicks (*Transactions of the Obstetrical Society of London*, 1871) divided the anterior wall of the vagina before the birth of a child, and removed a fibroid tumour growing from the front wall of the vagina, completely blocking up the pelvis, and preventing delivery. The result was good.

In the removal of fibroids unconnected with child-bed, Atlee advised the complete extirpation of the tumour; whereas Baker Brown was content with mutilating or mincing it up.

Sims (*Clinical Notes on Uterine Surgery*, London, 1866) operated four times, twice after Atlee's plan, and twice after Brown's, and lost a patient by each plan. He states that the operation should never be undertaken except when the patient's life is endangered from loss of blood. [This opinion he reiterates in his last pamphlet, noticed in the LONDON MEDICAL RECORD, September 2, 1874.—*Trans.*]

Retzius (*Neue Zeitschrift für Geburtskunde*, Band xxxi. 1851) in a case of fibroid containing calcareous concretions, bored into the tumour with a perforator in order to make it compressible, and to be able to incise the os; he drew it down by means of Davis's craniotomy forceps, enucleated it with the knife, and then reduced the uterus. With all this, he nevertheless obtained cure.

Langenbeck (*Deutsche Klinik*, no. 1, 1859) dilated the os for eight days with sponge-tents, then inserted a double hook into a sessile fibroma of the size of a hen's egg, situated on the posterior wall of the body and neck of the uterus, slit up the posterior wall with a long incision, and shelled out the tumour with the fingers and scissors. The patient recovered.

Baker Brown divided the operation into two parts. The first consisted in slitting up the cervix bilaterally with the metrotome, and plugging the incised cervix with oiled cotton-wool. The patient was then left for fourteen days, in order that the cut edges might heal, so as to obviate the danger of purulent absorption from the raw surfaces. In the second stage of the operation, he introduced his forefinger as high up as the internal os, then passed a pair of curved blunt-pointed scissors up to the tumour, pressed gently against the capsule, opened the blades, and withdrew a small portion of the tumour; oiled pledgets were then placed in the remains of the tumour, and the vagina was well plugged. He called the second operation 'gouging.' Out of fourteen operations he lost two patients. The latter half of the operation he did not always esteem necessary, as the incision alone frequently checked the hæmorrhage, and at times

arrested the further growth of the tumour, and even effected not only a diminution of the fibroid, but its complete disappearance.

Matthews Duncan (*Edinburgh Medical Journal*, February, 1867, and November, 1870) removed fibroids from the uterus successfully five times. In the first case he dilated the cervix with laminaria and sponge tents, then incised it, extracting a fibroma measuring two inches. In the second case he enucleated a fibroma three and a-half inches long, in the third one five inches long, and in the fifth case a fibroma reaching as high as the umbilicus. In this last instance incisions were made into the os, which was dilated to the extent of an inch, and the tumour was seized with two hooked forceps, drawn down and shelled out. After one hour, the part lying at the vulva could be fixed by a loop; and at the end of two hours, by the division of two strong bands of union, the whole tumour was detached.

Barnes enucleated an uterine fibroma successfully, in 1865 (*Obstetrical Transactions*, vols. v. and vii.).

Scott (*Edinburgh Medical Journal*, October, 1868) enucleated successfully a fibroma weighing two pounds, seven inches long, and twelve inches in circumference. The os, which was dilated to the size of a half-crown, was slit up; the tumour was first detached with the fingers and uterine sound, then one half was removed by the écraseur and the other by the hand.

Gusserow (*Monatschrift für Geburtkunde*, Band xxxii. 1868), removed from the anterior wall a sessile fibroma weighing 260 grammes (more than nine ounces); it was about four inches wide and two thick. The os was incised bilaterally; at the end of four days extraction of the tumour was attempted in vain; after another four days, the rents made by the forceps were dilated and the growth was in part turned out. It was only at the end of five more days that it was entirely removed by the scissors on account of gangrene.

J. Hall Davis (*Obstetrical Transactions*, vol. x. 1868) removed an anterolateral sessile tumour weighing eighteen ounces, and having an attachment from the cervix to the fundus on the right side. The fibroid was first detached as far as about half its height, and a piece weighing six and a-half ounces was removed by ligature. The other half was cut in several directions, and about three-and-a-half ounces were removed; the remainder was expelled spontaneously on the fourth day.

Whiteford, in 1870, successfully removed a fibroma seated in the anterior wall of the uterus, after dilatation of the cervix (*Edinburgh Medical Journal*, February, 1870).

Chrobak (*Wiener Mediz.-Chirurg. Rundschau*, 1871) removed from the fundus a sugar-loaf sessile fibroma nine inches long, and a little more than nine inches in circumference. The uterine sound entered about 3½ inches. Six incisions were made into the vaginal portion of the cervix; three days afterwards a platinum wire was looped over the growth, and on the next day a piece about the size of a fist was taken away by the wire being made red hot; this was followed by two severe hæmorrhages. No attempt appears to have been made at enucleation by the fingers. Three weeks afterwards a ligature was placed on the tumour close to the uterine walls, and on account of the ichorous discharge the tumour was completely cut through. On the second day and later on, the remainder of the growth was

lessened by the polypus-forceps. After recovery, the uterus only measured $2\frac{3}{4}$ inches.

Männel, of Dresden (*Prager Vierteljahrsschrift*, Band cxxii. 1871), removed a fibroid reaching up to the navel successfully, after repeated operations. The vaginal portion of the cervix was 0·8 inch long, and the orifice was small; the uterine cavity was about 5 inches long. By means of bilateral incisions of the cervix the finger could be introduced in June, 1870, and the capsule of the fibroma divided with Sims's hysterotome to the extent of 1·6 inches. Enucleation was abstained from. During September, October, and November oblique incisions were repeatedly made with the scissors, with fruitless attempts at enucleation. The os was about two inches wide, and the tumour could be encompassed to the height of two inches. In May, 1871, a portion weighing 107 grammes (rather more than $3\frac{1}{2}$ ounces) was cut off with the scissors, and removed with hooks. In September, 1871, again, 125 grammes were amputated. In all, 232 grammes (eight ounces) were taken away; a portion remained, which, in the succeeding two years, had increased in width, and caused menorrhagia.

In October, 1870, Männel enucleated a fibroma, weighing 490 grammes (about seventeen ounces) during one sitting, with good result.

Spiegelberg, in 1873, recommended extirpation in cases of irreducible encapsuled tumour, growing from the wall of the uterus into the vagina, partly or entirely filling the pelvis, and causing much distress by pressure. He operated unsuccessfully in three cases (*Archiv für Gynäkologie*, 1873, band v.).

Müller of Würzburg, in 1873, in four cases of large fibromyomatous tumours of the vagina, springing from the cervix, observed healing and diminution of the remainder of the fibromata from merely chopping off a portion without enucleating them.

Breslau (1865) and Spiegelberg (1873) have collected sixteen cases from literature and their own observation, where Cæsarean section had been performed for fibroma; in all instances, the result was fatal (Gensoul, Kilian, Thibault, Montgomery, Charles Waller, Lehmann, Faye, Pillore, Breslau, Legouvais, Huguier, Depaul, Stoltz, Spiegelberg).

For the elucidation of this most important question of enucleation of uterine fibroma, Dr. Braun-Fernwald relates six observations of his own in which complete restoration was attained.

The first patient was a widow, aged thirty-six. The whole of the pelvis, as far as the vestibulum, was filled with a firm smooth tumour, reaching above the inlet as high as the navel, measuring nine inches long by four inches. The part lying beneath the abdominal parietes was an equal segment of a sphere; and above this to the right side a small tumour, of the size of an orange, was perceptible; this was suspected of being the fundus and body of the uterus without any thickening of its walls. The hand introduced into the vagina could not reach as far as the greatest circumference of the tumour. The galvanic wire cautery was passed up about four inches, and a portion of that dimension cut off; a red heat was maintained for forty minutes, without once breaking the wire. The detached piece was then seized by the cephalotribe, squeezed, and divided in its oblique diameter with Siebold's scissors, along the anterior margin of the blades. The posterior quarter was first withdrawn by the cranioclast, and then the anterior one. The upper half of the fibroma was now fixed by the cranioclast, and for the most part

detached from its capsule, within the exception of a few thin bands, which were cut through by the wire cautery. The platinum wire was placed as high up as was possible. After the removal of the tumour, which weighed six Vienna pounds (seven and a half English), there remained in the left half of the cervix a piece of capsule of the size of a fist, which hung down like an empty purse. The uterus could not be entered through it, but as soon as the finger was passed outside it, the internal os could be reached, and the uterine sound introduced an inch and a half. The tumour consequently grew from the cervix and not from the body of the uterus. A glycerine plug was placed in the vagina, and changed twice daily. No fever of reaction occurred. At the end of four weeks the cervix was completely restored, and the vaginal portion normally formed. The whole uterus measured three inches long by one wide.

The second case happened in a woman, mother of twelve children. Her last pregnancy occurred eight months previously, and since then there had been a continuous bleeding. A fibroma of the size of an apple, and firm consistence, was found in the vagina; it diminished above and became softer. The vagina passed directly into the tumour. Bimanual exploration failed to discover the uterus. An inverted uterus, with an orange-sized fibroid, was diagnosed. A piece of the size of a walnut was cut off by the galvanic cautery. During the next ten days, the purulent discharge from the remaining myoma and its cedematous condition rapidly increased. The remainder of the fibroma was therefore removed by the galvanic cautery, without injury to the peritoneum. Thereupon spontaneous reduction of the inverted uterus took place. The cervix soon contracted, the body of the uterus remained about the size of a walnut, and there was no more hæmorrhage. The woman had a slight attack of pleurisy, but quite recovered.

The third case was in a sterile woman, aged forty-one. A large cystic myoma springing from the body of the anterior wall of the cervix and the vagina was diagnosed; it extended to the middle of the pelvis and about three inches above the inlet. The tumour was seized by Küchenmeister's forceps, and the galvanic loop passed round its greatest circumference. The portion of tumour removed was full of cysts of the size of a hazel-nut, containing clear grey gelatinous matter. Through the contractions of the uterus, a second part about the size of an apple was expelled into the vagina, and was removed. A further enucleation of the tumour was not attempted, on account of the proximity of the bladder. After a rest of eight days, a third portion of the tumour was detached by the galvanic wire and the finger, as far as the fundus uteri. There was some fever before the third operation, which immediately subsided, and the patient made a complete recovery.

The fourth case was in an unimpregnated woman, aged thirty-four. The tumour extended from the inlet to the umbilicus, about the size of a head, seven inches long, and was immovable. The os was 0·4 inch wide, with a sharp anterior lip and a blunt posterior one. The uterine sound passed five inches into the right side of the uterus. High rectal exploration discovered a fibroma arising from the posterior lip. With Jacquemier's decapitation-instrument, which was slightly bent, several cuts were made through the capsule, dividing it to the extent of about two inches in the cervix, and for one inch through the portion arising from the vagina. The

cervix was divided bilaterally, and with the fingers the tumour was separated from its capsule for about its lower half, and then seized with the cranioclast and compressed. Its extraction still being impossible from its great size, the cervix was further slit up with Heywood Smith's angular scissors, and by aid of Böer's fenestrated placental forceps, and a few turns of the instrument to the right, by which means the upper half was completely turned out; it was forthwith extracted. A cotton-wool plug dipped in glycerine was introduced into the vagina, and changed twice daily. She recovered without a single bad symptom, and went out perfectly well.

The fifth case was in a newly married woman, aged thirty-six. A tumour, of the dimensions of a child's head, was found protruding from the vagina. On reducing it, there escaped several pints of purulent secretion. A rectal examination showed a tumour filling up the whole of the pelvis and extending two inches above its brim. On its upper surface was attached a small body, about the size of an orange, the body of the uterus. The tumour had spontaneously burst through its capsule. The platinum wire-loop was passed over the tumour as high up as possible, and tightened until it had nearly cut through the pedicle, when the galvanic battery was applied, and the tumour was rapidly completely detached. It was extracted by the cranioclast, after having been reduced by compression. The cervix was about as large as a fist after its removal, but the internal os was not passable to the finger. The woman quite recovered without any febrile symptoms.

The sixth case was in a multipara, aged forty-nine. The tumour, which was about the size of a child's head, sprang from the cervix, dilated the external orifice, and extended beyond the upper third of the vagina. The fibroma was seized with Courty's hooked forceps, and the platinum wire-loop passed round its largest part and made red-hot. By this means its capsule was cut through, and a piece as large as an orange removed. The upper half was then detached with the finger from its capsule, and extracted with the cranioclast. The woman recovered.

In these six cases the tumours grew twice from the cervical wall and the body of the uterus, three times from the cervix and vagina, and once from the fundus of an inverted uterus. In all six instances Dr. Braun-Fernwald operated according to Atlee's advice. In four cases the tumour was removed at one sitting, once in two sittings, and once at three sittings. He calls this method extemporised (*extemporiserte*) enucleation. The galvanic cautery was employed five times, and Jacquemier's decapitation once, for opening the capsule. The cranioclast was used four times and the cephalotribe once for smashing up the tumour. The instruments used for the extraction of the foetus were in every case found quite sufficient. Preliminary dilatation of the cervix by laminaria or sponge-tents was not used. There was no hæmorrhage of any importance.

Professor Braun-Fernwald very fully reviews Dr. Marion Sims's latest mode of operating [detailed in the LONDON MEDICAL RECORD of September 2], but believes his plan of using the galvanic cautery very convenient and safe. He prefers Jacquemier's decapitator to the scissors for incising the capsule, as being more readily introducible through a narrow os. The glycerine tampon of cotton-wool was the only

medication he employed; it is used for the purpose of excluding the external air from the raw surface.

With his six cases and Marion Sims's eight, there are now sixty known cases with a mortality of 32 per cent.; recovery having taken place in forty-one. Since the experience of Péan and Köberle, and still later of Spiegelberg, in the successful removal of large interstitial and subperitoneal tumours by Cæsarean section, he thinks that the operation in future will become a recognised justifiable operation—an opinion held by Marion Sims.

W. C. GRIGG, M.D.

ANATOMY AND PHYSIOLOGY.

HERING ON SIMULTANEOUS LIGHT-CONTRAST.—In a recent communication to the Vienna Academy (*Sitzungsberichte*, no. 68) M. Hering discusses the subject. The following is an account of this investigation.

The action of simultaneous contrast may be had in a simple way, thus: A narrow strip of dark grey paper is held against a dark background, and a marked point of the strip is looked at; then a sheet of white paper is thrust between the strip and background, and the strip appears much darker than before; the white paper is then removed, and the strip seems immediately brighter again.

The spiritualistic explanation is, that we do not hold fast in our minds the first impression of the grey long enough to be able to recognise its identity with the second. Similarly, an ordinary man will appear big by the side of a dwarf, small by the side of a giant. We do not retain the man's size in memory sufficiently to be able to compare the later impression with the earlier.

This imperfect memory might be aided by changing the background very quickly; and the fact that the change of brightness is still observed seems to be against this explanation. But again, two phases may be produced together instead of successively. Two grey strips are cut about 0.16 inch wide, and their ends are connected with cross-strips, so that they shall be 0.48 inch apart; they are put on a dark ground, and a point midway between them is looked at. Then a sheet of white paper is pushed in with the edge always parallel to the strips, towards the point looked at. When it passes under one strip this darkens, and we may compare its brightness with that of the other still on the dark ground. The difference is here almost as striking as in the other case.

Accordingly, another explanation is sought. It is said that the comparison of the brightness of two images on the retina is more uncertain the further apart the two images are, and that the two strips appear different because the apparent brightness of each is judged according to the ground about it, not according to the other strip at a distance.

That this, too, is insufficient, is shown by the following experiment, based on the consideration that if the two parts of the retina corresponding to the two strips be differently excited, notwithstanding the same objective brightness in the strips, the 'after-images' must also be different.

Two strips are cut 0.12 to 0.16 inch long and 0.02 inch broad, and placed on a background half white half black, so that they are, on each side, parallel with the boundary line, and about 0.04 inch from it. A

point in the boundary line is looked at for half a minute to a minute. Then the eyes are shut and covered, and the after-image is observed. The bright part of the ground now appears the darker, the dark part the brighter; and the strips, too, show a different brightness, though they had an equal objective brightness; indeed, the difference in the after-image is greater than in the first image. Now the psychological explanation of this difference of after-images must be quite similar to that adduced for difference in the primary images; and it will be said, that the after-images of the strips seem different because they are on unlike grounds, the one on the previously more fatigued part of the retina, which is now therefore the darker, the other on the unfatigued part, which is now therefore the brighter.

But against this, there is first the fact, that the difference of brightness of the strips is greater in the after-image than in the first image; for a different brightness must, in both cases, only result from different brightness of the two halves of the ground; the greater this is, the greater must be that of the after-images (according to the psychological theory). If the difference of brightness of the strips, therefore, appear greater in the after-image, that of the grounds should be also greater; but this is not the case. It is soon evident that the increase or decrease of difference of brightness of the strips, in the after-image, does not go parallel to that of the two halves of the ground, but it is sometimes slower, and sometimes faster than this, and sometimes even in the opposite direction. It was repeatedly observed, that the difference of brightness of the strips in the after-image was, for a time, greater than that of the two ground-halves; that the brighter after-image of the strip appeared brighter than the bright ground-half, and the darker one darker than the dark ground-half. This cannot in any way be explained as a contrast phenomenon in the psychological sense. The paradoxical character of such a view may be seen from the above-cited example of an action of contrast. Suppose two men of equal size (the two similar states of excitation, or perceptions of the strips in the after image), and standing not far apart. Near one of them, suppose one or several giants (the brightness of the brighter ground-half); near the other, one or several dwarfs (the darkness of the darker ground-half). Under such circumstances, it is conceivable that the middle-sized man between the giants might appear somewhat smaller than the man of equal size between the dwarfs; but it is inconceivable that this apparent difference of size of the two ordinary men could be greater than the actual difference of size between the giants and the dwarfs themselves, and that so the ordinary man near the dwarfs could appear, in contrast with them, even bigger than the giants a short way off, and the ordinary man near the giants smaller than the dwarfs.

But any support of the psychological explanation is completely removed by the following fact. When the liveliness of the after-image has somewhat abated, there occurs a phase, in which the difference of brightness of the ground-halves quite disappears, but the after-images of the strips are quite distinct, and the one appears brighter, the other darker, than the surrounding homogeneous ground. Here the question is not one of action of contrast, because the condition of such action, viz., the different brightness of the ground, is no longer present.

We are brought to the conclusion, that in the first

image the objectively similar strips appear different, because the two corresponding parts of the retina are in different states of excitation. Simultaneous contrast rests on the fact that the sensation of light by a part of the retina depends not only on the illumination of the latter, but also on that of the rest of the retina. The grey strip appears darker on a white than on a black ground, because the excitability of the corresponding part of the retina is diminished by the simultaneous strong illumination of the surrounding portion.

The action of contrast decreases with the distance from that part of the retina from which the darkening is induced; as may be proved by the following experiment. Two strips of grey paper are placed on a dark ground, parallel to each other, and about one centimetre apart. Midway between them a mark is made. The eyes having been kept shut some time, this mark is looked at, and a white sheet is brought from the side towards one of the strips. This strip will forthwith seem distinctly darker than the other. Next the sheet is brought to the other side, and advanced towards the other slip; the latter will then look the darker.

The method of observing simultaneous contrast by means of after-images has this advantage, that the images are much purer than those of the open eye. In the after-image of a paper strip, e.g., we do not see the texture of the paper, nor its slight folds and creases, nor specks, nor fibres; in a word, we do not see a piece of paper standing out from its ground, but only a piece of the field of vision, which is illuminated differently from its ground.

MAYER ON THE PHYSIOLOGY OF AUDITION.—In no. 46, vol. viii. of the *American Journal of Science and Arts*, and also in the *Philosophical Magazine*, Mr. A. M. Mayer is publishing his 'Researches in Acoustics.' The fourth section of article 21 (in the *American Journal*) is occupied with *Deductions from these (acoustic) laws leading to new facts in the Physiology of Audition*, and therein he says that the immediate consideration of the laws he has established gives the most convincing confirmation of Helmholtz's ideas of the high differentiation in the dynamic constitution, or mechanism of the ear. The very fact of the ear's power to effect a sonorous analysis was shown by Helmholtz to be a proof of this; but our physiological law, susceptible of a mathematical expression, affords the most direct proof that one could desire of the existence in the ear of a highly differentiated mechanism, so differently affected in its different parts by sounds of a different pitch. Helmholtz, even from his restricted premises—which Mr. Mayer has enlarged—divined this, and says (*Tonempff.*, p. 215), 'As the difficulty of making a trill in the bass is the same on all musical instruments, and as it is evidently altogether independent of the mode of production of sound on each instrument, we have to conclude that we have here to do with a difficulty which resides in the ear itself. Here is a phenomenon which neatly proves that the vibrations of the mobile parts of the ear for bass sounds are not "damped" sufficiently, or quickly enough, to prevent two sounds to succeed each other so rapidly without blending.'

'This fact proves, besides, that there should be in the ear different parts which are set in vibration by sounds of different height, and which give the sensations of these sounds. Some may imagine that the mass of the vibratile elements of the ear, comprising

the tympanic membrane, the ossicles, and the internal ear, can vibrate, and that it is on this property of this mass that depends the impossibility of sonorous vibrations ceasing with the same rapidity in the ear. But this hypothesis does not suffice to explain the known facts.

'When, in fact, an elastic body enters into vibration under the influence of an exterior sound, it takes the number of vibrations of the latter; but, as soon as the exciting sound ceases, it vibrates with the number of vibrations which belong to it when vibrating freely. This fact, which is a consequence of theory, can be very neatly proved for tuning-forks by means of the vibration-microscope.

'Therefore, if the ear vibrate as an entire system, and be capable of prolonging notably its vibrations, this prolongation should depend on the number of its own free vibrations, which is altogether independent of the number of vibrations of the exterior sound, which excited the vibratory motion. It at once follows that it will be as difficult to trill among the high notes as among those of the bass, and, also, that the two sounds of the trill will blend, not with each other, but with a third sound belonging to the ear itself. We have already made known one of the sounds in the preceding chapter: it is the fa_6 (French notation.) In these circumstances, consequently, the result should be altogether different from that given us by the observation of the facts.' [In a note Mr. Mayer says that the fact to which Helmholtz refers is that the human ear is tuned by resonance, to the fa_6 , of 2,730 complete vibrations; so that the vibrations of this note, and of those near it, cause piercing sensations in our ears. If a short tube be adapted to the external auditory canal these disagreeable sensations disappear, as the canal can no longer resound to the above note; but the same piercing sensation will now reappear on sounding a lower note.] Madame E. Seiler, of Philadelphia, has shown that dogs are peculiarly sensitive to the acute *mi* of the violin. If we extend our law downward and upward, throughout the range of audible sounds, we have for forty vibrations per second a residual sensation lasting $\frac{1}{11}$ th of a second; while for 40,000 vibrations per second we have a residual sensation enduring only $\frac{1}{500}$ th of a second. If we apply the law to vibrations below forty per second, when they do not produce a continuous sound, but explosive sensations in the ear, we reach a remarkable result. Thus, the residual sensation, corresponding to thirty vibrations per second should remain in the ear $\frac{1}{10}$ th of a second, after the vibrations outside the ear have ceased; then we at once ask why it is, if the residual sensation lasts $\frac{1}{10}$ th of a second, that thirty beats or pulses per second do not blend? Do not three distinct impulses fall on the ear in each $\frac{1}{10}$ th of a second? For they follow one another at thirtieths of a second. This abrupt breaking down of the law can only be explained by the highly probable supposition that co-vibrating bodies in the ear, tuned to vibrations below forty per second, do not exist, and therefore, as there are no bodies in the inner ear to co-vibrate and keep up these oscillations, after the cause which would have set them in motion has ceased to exist, it follows that when the ear receives less than forty vibrations per second it can only vibrate *en masse*, and the duration of these oscillations of the ear, as a whole, is far too short to remain the $\frac{1}{30}$ th of a second. The last supposition as to the vibration of the ear as a mass may serve to explain why the higher notes—far beyond those used in the musical scale—produce

continuous sensations. For to those very high sounds we can hardly imagine corresponding tuned bodies; yet they produce continuous sensations. But may it not be imagined that the ear with them does also only vibrate as one mass, and that the duration of this vibration is sufficient to give continuous sensations from pulses following at the rate of several thousand per second? But for notes thus perceived, without the intervention of corresponding co-vibrating parts in the inner ear, differences of pitch should be difficult, even impossible, to distinguish, and this we find to be the case.

(To be continued.)

MARTINS ON THE COMPARATIVE OSTEOLOGY OF THE FORE LIMBS OF THE MONOTREMES.—M. Martins, well known for his researches into the torsion of the humerus, contributes a note to the last volume (xix.) of the *Annales des Sciences Naturelles, Zoologie*, 1874, upon the osteology of the fore limb of the ornithorhynchus and echidna as compared with the corresponding member in reptiles and birds, and in other mammals. The skeleton of some birds, e.g., a fowl or pheasant, must be placed by the side of that of an ornithorhynchus or echidna, in such wise that both are in the position of a flying bird, the sterna being in the same horizontal plane. The humerus of the monotreme being naturally directed horizontally, and perpendicularly to the vertebro-sternal plane, the corresponding bone of the bird is brought into the position assumed when the wing is depressed in flight; after which, the forearm is caused to make a right angle with the humerus, as is the case with that of the monotreme. The limbs of the animals being now in the same position, one can proceed to institute comparisons. It will first be remarked that the humerus of the monotreme is not twisted to 180° , or two right angles, as it is in other terrestrial and aquatic mammals. Owen has already remarked this degree of torsion, and estimates it at half a circumference. This is indicated in the two monotremes by the direction of the crest of torsion, which, starting from the epicondyle of the humerus, comes to terminate below the head of this bone, without having, as in the other mammals in which the amount of torsion of the bone is about 180° , twisted *en hélice*, the half of the thickness of the body of the humerus. The upper extremity of the humerus of the monotreme resembles that of the bird, not only in general shape, and in the direction of the axis of its neck, but in having an 'os humero-capsulare,' as Nitzsch discovered, articulated with it and the coracoid bone. At the inferior extremity of the bone all resemblance ceases.

With regard to the bones of the fore-arm in the monotremes two things will be remarked. 1. The radius and ulna do not cross one another, and the fore-arm consequently is not in a state of pronation, as in other mammals. 2. The ulna; parallel to the radius, lies on the outside, and not on the inner side and behind, as in other mammals. In the bird we remark the same peculiarities; the ulna, like its homotype the fibula, lying to the outside, while the radius, homologue of the tibia, is on the inner side. In other mammals, on the contrary, even when the forearm is not pronated, its two bones are not parallel, the superior extremity of the radius being on the outside, while the inferior is on the inner side. Further than this, in monotremes, as in birds, the fibula articulates with the femur; but the latter have not, as the monotremes, a peroneal apophysis which rises above the fibulo-femoral articu-

lation, nor a mobile tibial 'rotula,' representative of the bifid olecranon of the fore-limb. If the skeleton of some reptile, e.g., a lizard, be placed by the side of that of a monotreme, the same analogies will be found, for the humerus of the reptile, twisted to 90 degrees, bears a striking resemblance to that of a monotreme; but the fore-arm of the reptile being in a state of pronation, its two bones cross one another, the head of the ulna being within and behind, while that of the radius lies to the outer side and in front. Though the fore-arm of the bird has the greater resemblance to that of the monotreme, the manus of the latter has a greater likeness to that of the lizard, and more than this, to that of certain of the higher mammals, e.g., the manus of the amphibious ornithorhynchus to that of the otter, and the same member in the echidna to that of the fossorial mole. With regard to the scapula of the monotreme, though the spine seems to be wanting, M. Martins believes, with Cuvier, that it is fused with the front margin of the bone, for this terminates anteriorly in a true acromion, which articulates with the furcular bone. [If we are not mistaken, Mr. St. George Mivart has been led by myological evidence to the same conclusion. See his paper on *Echidna Hystrix* in the *Transactions of the Linnean Society*, vol. xxv.—*Rep.*] M. Martins believes, with Mr. Parker, that the shoulder-girdle, which has most in common with that of the monotreme, is the sternal apparatus of the ichthyosaurus. This is an important point for the evolutionist theory, as giving evidence of a common 'phylum' for reptiles, birds, and mammals.

The shoulder-girdle of the monotreme is finally discussed by Martins from the functional point of view. Seeing that of numerous mammals, which are fossorial, some, e.g., the mole, which seems to swim in the earth (*qui semble nager dans la terre*) have this apparatus reduced to a long episternal bone, and others have the clavicle either imperfectly ossified (e.g. the rabbit and armadillo) or do not retain the merest rudiment of this important bone (e.g., the badger and pangolin), while in an animal exclusively pelagic, such as the ichthyosaurus, the sternal apparatus is most complicated, it is evident that the complex shoulder-girdle of the monotreme has no functional purpose to serve, but must rather be regarded as an heirloom derived from an ancestral ichthyoid reptile.

JEHN ON EXTENSIVE CAPILLARY EXTRAVASATION OF BRIGHT RED BLOOD INTO THE PULMONARY TISSUE OF THE INSANE.—Dr. Jehn (*Centralblatt für die Medicinischen Wissenschaften*, no. 22 refers to Nothels observations upon hæmorrhage into the lungs coincident with injury to the brain (*Journal of Anatomy and Physiology*, viii. 397), and cites five cases of his own (one case of melancholia one of mania, three of paralysis) where in the lungs extravasation of bright red blood, completely resembling arterial blood, were found. The patches

were sometimes distributed, and in one case the extravasation was almost total. The boundaries were irregular but sharp, the bronchi were free. Microscopically the alveoli were almost exclusively filled with red-blood corpuscles, no changes were to be observed in the vessels and pulmonary tissue. The pathological results in the nervous system were partly negative, partly old and fresh meningitic new formations, hæmorrhagic pachymeningitis, diffuse nodding of single gyri, in two cases apoplexy of the grey matter of a capillary nature. During life no manifestation of the lung-affection was exhibited. [See also the LONDON MEDICAL RECORD, no. 74, 1874, for a series of cases with remarks taken from the *Progrès Médical*.—*Rep.*]

RIVERS ON RATTLESNAKE-POISON. — In *The Southern Medical Record*, September, 1874, Dr. S. M. Rivers relates several cases of snake-bite, in one of which death took place within three hours after the reception of the poison. He describes the effects of the poison as those of a narcotic sedative, consisting of an intense burning in the wound, extending over the body, even to the top of the head; vertigo, nausea, and vomiting, dimness of vision, irregular spasmodic action of the muscles; then delirium, relaxation, depression of the vital powers, and death by syncope. The only reliable remedy is powerful alcoholic stimulation in conjunction with ligatures above the wound, and suction by means of cups or the mouth directly over it.

ELIAS ON OBLITERATION OF THE VENA CAVA INFERIOR AND VENA PORTÆ BY AN ENORMOUS HYDATID CYST OF THE LIVER; ASCITES; PARACENTESIS; POST MORTEM EXAMINATION.—In the *Berliner Klinische Wochenschrift* for November 16, the following case is described by Dr. Carl Elias, of Breslau. E. G., aged forty-two, of independent means and healthy parentage, suffered at the age of twenty from a tertian ague for nearly eight months; from typhoid fever seven years later; and in the spring of 1866, from pains of a 'rheumatic' character in the left lumbar region. Soon afterwards his left leg swelled a good deal, but after six weeks, and the use of warm baths, it gradually decreased in size. In the autumn of the same year he noticed considerable enlargement of the cutaneous veins of the anterior part of the thorax, and soon afterwards felt a tumour in the left side (through the abdominal walls) just below the last rib. The abdomen enlarged and

became tense. Pricking pains set in, radiating from the region of the spleen, and so severe as often to deprive him of sleep. His general health became affected. The bowels were constipated, but his appetite was good. His condition when first seen was as follows. There was considerable emaciation. The skin and conjunctivæ were slightly jaundiced. The belly was swollen, cylindrical, and tense. The umbilicus protruded in a bullet-like form. The left side bulged out considerably. The lower extremities were much swollen. The circumference of the abdomen at the navel was $42\frac{1}{2}$ inches, at the xiphoid cartilage 46 inches. Inspection showed enormous development of the cutaneous veins of the thorax and abdomen, especially in the epigastric region, displaying the *caput Medusæ* in a way rarely seen. The veins were distended and tortuous, with a deep-blue tint, rendered still more striking by the yellow tinge of the skin. The most developed were the internal mammary and epigastric veins; the latter, just above the groin, had a thickness of three-eighths of an inch. Percussion on the right side showed dulness commencing at the third rib, in a line with the nipple; and this was demonstrable over the hepatic region, to within about $1\frac{1}{2}$ inch from Poupart's ligament; then there was a clear tone from intestine; and similar percussion-notes in the right axillary line. Over the sternum, dulness began at a level with the fourth rib. The percussion on the left side was normal to the third rib: here the cardiac dulness began. From this down to about two inches from Poupart's ligament there was dulness, and in a line with the left axilla it was much the same. Posteriorly, percussion was normal to the fifth rib on the right, and the sixth rib on the left side. Breathing was healthy at the apices. There were no signs of cardiac disease. The arteries were small, and their tension slight; the femoral artery was scarcely to be felt. There was much ascites. The patient had considerable dyspnoea, præcordial anxiety, and severe pains in the abdomen, with constipation and anorexia. The urine was scanty and slightly albuminous. Notwithstanding the tension of the abdominal parietes, a large tumour was clearly perceptible, the pressure of which on the great vessels had induced the exudation. To relieve dyspnoea, and clear up the diagnosis, Professor Fischer tapped and drew off nearly a gallon of clear serum. The tumour with its inequalities was now very evident—its history, size, character, and apparent connection with the liver, indicated a polycystic hydatid tumour of that organ, demanding operative interference. His breathing was much relieved by the operation; and sudden acute pains near the left shoulder were relieved by hypodermic use of morphia, after which he slept for several hours. In the evening he was very weak, collapse set in, and he died eighteen hours after the paracentesis.

The *post mortem* examination was made twenty-four hours afterwards by Dr. Waldeyer. The liver was found immensely enlarged, extending downwards to the ilium and above to the third rib, filling both sides of the abdomen, and projecting forwards. The apex of the heart was at the level of the third rib on the left—being pushed up by the tumour; the stomach and spleen lay on the left, pushed upwards. The lower side of the liver was occupied with a colossal cyst, reaching to the extent just described. This was divided into two by a thin partition, and each division was a large parent (mother) hydatid cyst, containing a quantity of clear fluid and nume-

rous scolices. The left cyst had a diameter of about eight inches; the right one of about fourteen inches. Both were nearly globular. They rested on the posterior abdominal wall and vertebral column; and the liver, which was flattened out, floated over them. The gall-bladder was somewhat flattened and distended, but the ducts were pervious. The hepaticoduodenal ligament was greatly flattened, and six inches long. The main trunk of the mesenteric vein was impervious, and its coats were thickened. The vena portæ for nearly two and a half inches was a mere flattened cord, scarcely distinguishable from the cyst. On both sides of this obliteration it was pervious, and admitted the index-finger. There were no thrombi in the tributaries of the mesenteric vein. Near the obliterated trunk of this vessel there was another vein of nearly equal calibre, close to the gall-bladder, composed of branches from the pancreas and stomach, and passing directly into the parenchyma of the liver. The thoracic part of the vena cava inferior was normal. The diaphragmatic veins were dilated; the hepatic partly flattened, partly impervious. The vena cava, from the diaphragm to the iliac veins, was perfectly obliterated. The left renal vein was in connection with veins of the anterior wall of the abdomen. Other anastomoses were recognised between the renal and diaphragmatic veins, and those of the posterior abdominal wall. The liver itself was slightly enlarged—particularly the right lobe—but flattened out.

In commenting on the case, Dr. Elias remarks that hydatid cysts are a very rare cause of obliteration of the large abdominal veins, vena cava, vena portæ, etc.; crural phlebitis, thromboses, caries of the spine, aneurism of the abdominal aorta, the presence of other tumours are the common causes. Ott reports a case of flattening and partial obstruction of the calibre of the vena cava by a hydatid cyst of the liver. The vein was, however, not completely blocked. Obliteration of the vena portæ itself is not very common, as shown by Stannius and Puchelt's researches. The symptoms in this case pointed clearly to obliteration of the vena cava in life, but there were no positive signs of the obliteration of the superior mesenteric vein. Bidder and Schmidt's experiments on animals showed this to be rapidly fatal, if sudden. More gradual compression, as by phlephlebitis, induces blood in the stools and in vomited matter, as shown by Schönlein and Frerichs, and by Botkin and Leyden. Gintrac, in his work on *Obliteration of the Vena Portæ*, has shown that there was previous cirrhosis in most of his cases. Frerichs dwells especially on the rapid re-accumulation of fluid after tapping; here there was no time for this to occur. There was no sugar in the fluid of this case. [Jaffé found this in Leyden's cases.] The large vessel accompanying the obliterated mesenteric vein in the case may have caused absence of characteristic symptoms. Rokitsky points out that the anastomoses of the vena portæ with the branches of the internal iliac vein, vena azygos, and vena azygos minor, carry on the collateral circulation. Knox injected air through the azygos veins, and it passed through the intercostal and lumbar veins into the cava. Reynaud mentions also the anastomoses of the epigastric and mammary veins, of the subcutaneous abdominal veins with the axillary, with the hepatic, phrenic, veins of the posterior part of pelvis, and even the spermatic, and those of the ureters in exceptional cases. In the case above, the renal veins also assisted. Boyer and Cruveilhier show

that sometimes abnormally free communication between the portal and abdominal veins is congenital. [The reporter has seen three such cases. In two of them, the widely dilated veins of the front of the abdomen and thorax attracted attention almost immediately after birth. In these cases there was nothing worse than the disfigurement.—*Rep.*]

W. BATHURST WOODMAN, M.D.

FREY ON A CASE OF SUBACUTE DIFFUSED SPINAL PARALYSIS.—This case of general spinal paralysis, which occurred in the clinique of Professor Kussmaul, is related by his assistant, Dr. Anton Frey, in the *Berliner Klinische Wochenschrift*, November 2 and 9, 1874. Dr. Frey designates it as probably subacute inflammation of the anterior grey matter of the spinal cord—*poliomyelitis anterior subacuta*. Caroline H., seventeen years of age, of a healthy family, with no hereditary tendency to nervous disorder, of average bodily and mental development, was admitted in the winter session of 1873-74. With the exception of occasional headaches, she passed through her period of schooling without any illness. In March, 1872, she had, without any known cause, suffered from functional impairment of vision of both eyes, so that she could scarcely see even near objects. This affection yielded in about a month, under the administration of Calabar bean. Menstruation occurred at the age of fifteen, at first regularly; then, since the age of sixteen it had recurred every three weeks. Her occupation consisted, during the summer months, in light field-work, and during the winter in needle-work, knitting, etc. In March, 1873, she began to experience weakness in the hands, so that she could not do her knitting and spinning as before. She suffered also at this time from headache and anomalous sensations, for which she had recourse to baths, from which she derived some slight benefit. In September, 1873, all these symptoms became so rapidly worse that she could no longer perform domestic work. The hands became clenched, and only towards evening could the fingers be extended. Extreme weakness of the arms followed until it became impossible for her to raise them. About the middle of the same month, the lower extremities also were so much enfeebled that she could no longer maintain the erect posture or rise from her seat. The integuments of both upper and lower extremities became blue and cold: the soles of the feet were bedewed with cold sweat. Soon afterwards the limbs suffered from formication, and movements of the head were attended with pain. The patient also experienced difficulty in moving the globe of the eye and the tongue. The functions, moreover, of respiration, digestion, defecation, and micturition were rather impaired, and some degree of fever was present. By the end of September the paralysis reached the point at which it remained for two months. During this period the patient noticed that her upper extremities were becoming wasted. She shortly afterwards came under the care of Dr. Schmidt, who applied electrical treatment. By January, 1874, the galvanism had so far improved her condition that she could with some effort walk a short distance, could stand, and could rise from her seat; her arms had become so much stronger that she was able to do common housework, but her fingers had not free enough action to enable her to do needle-work, knitting, etc. The hands were strikingly wasted, and the susceptibility to electrical stimulus

much diminished. The treatment, at this time, consisted of daily Faradisation of the paretic muscles, and galvanism applied to the spine. In about six weeks she had improved greatly as to all the symptoms, and complained only of pains in the legs, arm, and back. Her general appearance was healthy. In respiration she expired only about half the average quantity of air. This feebleness of respiration probably accounted for a certain slowness of speech that was noticeable. A deep curvature of the spine existed in the lumbar region. The arms hung loosely, and their posterior surfaces were cold and discoloured blue. Many of the muscles of the upper extremities were much wasted (these are given in detail, too long for quotation), and their functions were greatly impaired. Testing the muscles of the forearm and hand both by galvanism and by faradisation showed great loss of electrical excitability. Several of the interossei, both abductors of the thumbs, and the triceps brachialis were wholly unaffected by electricity, and the biceps much less so than usual. The lower extremities were fairly nourished, and manifested no marked functional deficiency, although the feet were spread apart and turned outwards in standing. The integuments below the knee were cold and blue-looking. The intestinal functions were normal and menstruation occurring regularly. Under the influence of galvanism the muscles of the back regained power. By the following July the patient had so far recovered as to be occupied all day in domestic work.

In the preceding case it is to be noticed that a young and apparently healthy female, without any known cause, became the subject of a progressive and extensive paresis; and that within six months the patient had so far recovered that she could resume her domestic employments. The diagnosis in this case is founded upon three principal points which Duchenne, in 1853, laid down as characteristic of subacute general spinal paralysis. 1. Debility, and progressive paralysis of the voluntary movements generally, attack first the upper, then the lower extremities. 2. From the first, there is diminution or loss of electrical excitability in the enfeebled limbs. 3. Atrophy and fatty degeneration of the affected muscles appear. When it is observed, furthermore, that the cases related by Duchenne ran their course in a few months and were characterised by the absence of febrile or visceral disturbance, or of affections of the senses, it will be seen that the above instance coincides with the diagnosis of Duchenne. So far as the material is at present in our possession for the formation of prognosis, this is unfavourable, the paralysis extending to muscles deriving their nervous influence from the medulla oblongata. Even where the muscles have recovered their use, their electrical excitability remains deteriorated. In searching through the literature of analogous cases, it is evident, Dr. Frey observes, that this case would have been by many observers wrongly classed as one of progressive muscular atrophy, and, in illustration he refers to a case by Dr. Lange (*Virchow's Jahresbericht*, 1871), and to one by Friedreich (*Obs. vi.* in his work on Muscular Atrophy). When the patient above referred to was received into the institution, the case was, in the first instance, regarded as one of progressive muscular atrophy. Here was seen a wide-spread paralysis with wasting of the muscles, especially of the upper extremities, and manifested more especially in the muscles of the hands. The sensorial and psychical attributes were unaffected. The

digestive functions and the action of the sphincters unimpaired. All the symptoms seemed to point to progressive muscular atrophy. A closer investigation, however, and further electrical testing of the affected muscles, excluded the idea of progressive atrophy. In this case, after a state of general debility, the muscles of the upper extremities and of the trunk were in a short time attacked *en masse* by atrophy—a course different from that of progressive muscular atrophy, in which the small muscles of the hand are first affected, then the muscles of the extremities and of the trunk gradually become implicated, the morbid process extending over a year or more. The behaviour of the muscles under galvanism and faradisation is very different in the two diseases. In 'subacute general anterior spinal paralysis,' we find, as with the paralytic affection of the muscles, a complete and rapid insusceptibility to the electrical stimulus, out of proportion to the amount of atrophy. The reverse holds good with progressive muscular atrophy, in which the muscles more slowly lose their electrical excitability. An important practical difference between the two affections is also to be seen in the fact that the disease in the one case gradually and certainly extends to the medulla oblongata, tending to death; whereas, in the other, the subacute anterior spinal general paralysis, the prognosis may be favourable.

With reference to the pathology of this malady, or its seat in the spinal cord, observations are insufficient to determine this point. The closest analogy, Dr. Frey holds, obtains between this and spinal paralysis of the adult, both with reference to its pathology and symptomatology; with, however, this difference, that the latter is an acute febrile disease, whereas the disease shown in the preceding case is essentially non-febrile. In spinal paralysis a complexity of symptoms is reached in a few days, that does not occur in the disease under consideration until after the lapse of many weeks. In many respects, also, this affection resembles the acute spinal paralysis of infancy, which, from the researches of Charcot, Joffroy, and others, have been shown pathologically to be an acute myelitis of the anterior cornua. Hence, for these forms of paralysis, Professor Kussmaul suggests the name of 'poliomyelitis anterior.'

W. B. KESTEVEN.

WILHELM ON A CASE OF EQUILATERAL FACIAL PARALYSIS, TRISMUS, AND EXOPHTHALMOS.—This case is communicated by Dr. Wilhelm to the *Allgemeine Wiener Medizinische Zeitung*, Nov. 3, 1874. The patient was a young woman, reduced by nursing and anæmic. When first seen, she had paralysis on the left side of the face only, with bilateral exophthalmos, and paralysis of the abducens oculi. The patient was treated with galvanism, and left the hospital after about four weeks. She, however, returned in a few days, having completely lost the ground she had gained. She was extremely thin, entirely anæmic, and with a pulse of 120.

The left naso-labial fold was completely immovable; the left eye was prominent and congested; the cornea was ulcerated. A depraved condition of the motor portion of the fifth nerve was also shown by loss of sensation and motion in the soft palate, paralysis of the lips, and lock-jaw. The voice sounded weak, and was somewhat nasal. Application of the continuous current was followed by contraction of the levator alæ naris et anguli oris, and of the buccinator.

Notwithstanding the use of galvanism, the patient died suddenly a few days afterwards.

At the *post mortem* examination, the following appearances were found in the brain. The dura mater was thickened, the arachnoid rather opaque; the brain was much congested and soft; in its ventricles were about three drachms of clear serum. In the fourth ventricle, more particularly in its left wall, was a dry, cheesy, yellow mass, about the size of a hazel-nut, with a rough uneven surface; this protruded into the ventricle. In the right side of the ventricle was another mass about the size of a pea. The examination sufficiently explains the facial paralysis; but the trismus is not thereby sufficiently accounted for. The explanation of it which seems most plausible is, that the lock-jaw was consequent on the hyperæmia and waste which took place in the course of the fifth nerve.

[It is to be regretted that there is in this case no report of microscopical examination, either of the tumour or of the adjacent parts.—*Rep.*]

SURGERY.

SARAZIN ON THE ANTISEPTIC OCCLUSION OF WOUNDS BY NORWEGIAN TAR.—In a recent note to the French Academy (*Comptes Rendus*, Nov. 16), M. Sarazin states that after experimenting with various dressings, he has found vegetable tar (Norwegian tar) an excellent topic for wounds. The granulations formed under its influence are small, firm, and good-looking; the pus is thick and of good quality. This forms an emulsion with a small quantity of tar, which colours it slightly, and imparts its odour to it. When the tar is applied to the wound, it causes a slight burning sensation, comparable to that caused by alcoholised water. The teguments may remain coated with tar for any length of time without injury.

Solutions of tar in water, rendered alkaline by soda, have no unpleasant action on wounds, and they cleanse and disinfect rapidly. M. Boulé, of Bourges, prepares such a solution, containing 10 per cent. of tar without excess of soda, and without causticity. This is very suitable for washing wounds, and may be used with advantage to replace carbolic acid.

A piece of meat coated with tar, and covered with

a layer of wadding about a finger thick, and with a bandage moderately tight, which was also coated with tar, could be preserved three months in summer. The same experiment without the tar resulted in very rapid putrefaction; in six days the meat was diffuent and putrid.

M. Sarazin's method of dressing wounds is as follows.

The wound is washed with an injecting syringe with water containing about a third of tar liquor; then it is coated with a layer of tar, extending to the neighbouring articulations, if on the limbs, and to five or six inches from the lips of the wound, if on the trunk. A layer of wadding about two fingers thick is placed over (and a little beyond) the parts covered with tar. Some light pieces of wadding are put between the lips of the wound. The layer of wadding is then pressed and held by a bandage wound moderately tight. Warm tar is then spread over the whole dressing, and over this is placed a sheet of wadding round which a band is wound and held by several straps. This last part is for protection.

When it is wished to remove the coverings after ten, twelve, fifteen, or twenty days, the protective shell is taken off, and the tarry band cut with scissors. The cotton underneath is slightly yellow; its under layer is adherent to the skin, and at the edge of the dressing, in the space of about an inch, one cannot uncover the surface of the epidermis on which the tar is dried. A little further on, the under layer is detached, drawing with it the superficial scales of the epidermis, which form with the tar a dark, supple, resistant membrane. Near the wound this membrane, already detached to an extent variable according to the amount of suppuration, forms a pouch in which is collected the pus, usually neutral or acid, rarely alkaline. The skin, literally cleaned, is slightly ruddy, and covered with a fine pliant epidermic layer. Such is the adherence of this membrane to the skin, that, if the precaution be not taken to shave all the hairy parts, it cannot be detached without tearing out with it all the hairs, which is extremely painful.

So long as this artificial membrane is not cut or torn, there is only a slight smell of tar. When the pouch containing the pus is detached, the tar smell is somewhat modified; it is more acid, more penetrating, and less agreeable, without being essentially changed; it cannot for a moment be compared, even after three weeks, to the horrible stench from some wadding dressings.

The wound has, in general, a very good appearance. The author sometimes met with exuberant fleshy pimples, which he repressed with nitrate of silver. In general he merely washes with the tar water before re-applying the dressing.

M. Sarazin allows the dressing to remain on an average fifteen days; in summer, twelve, or even ten days, and when the pus is very abundant. He renews the dressing whenever he sees brownish spots forming on the dependent parts of dressing. An odour *sui generis* is then produced, recalling that of pus in the pouch already described; the latter has been fretted in consequence of the weight and pressure of the contained pus, which has filtered through the cotton. Even then, the putrefaction is not at all comparable to that with ordinary dressings of wadding.

While removal need not be rare, it is not neces-

sary to prolong the use of the dressing with antiseptic occlusion till complete cicatrisation.

The author does not think cotton indispensable. He has also used the tow of flax and of hemp, and oakum. He has sometimes used carded cotton of the finest quality, and sometimes the coarsest; the results are about the same. Cotton-wadding of good quality is perhaps the most suitable; the pressure is softer and the dressing more easy to remove.

He mentions about a dozen cases of amputation, etc., which he has treated in the above way. He has lost none of them, and has had no unfavourable symptoms.

In conclusion, M. Sarazin remarks that antiseptic occlusion by his method does not exclude immediate union. He then applies to the sutures a layer of collodion, before coating the parts with tar; and as it is necessary to remove the bandage the third or fourth day to take out the pins or the suture points, he dispenses with the second coating of tar (which is then useless). The method is altogether simple and inexpensive.

LANGENBECK ON EXARTICULATION OF THE HIP-JOINT, WITH FORMATION OF A POSTERIOR FLAP.—This operation, described by Professor Langenbeck in the *Berliner Klinische Wochenschrift*, for November 16, 1874, was performed on a man twenty-eight years of age, for the removal of the thigh-bone, from which sprang a large soft sarcomatous growth, extending down to, but not involving the capsule of the knee-joint. The method adopted by Langenbeck was as follows. First, the femoral artery was tied beneath Poupart's ligament, the limb enveloped in the 'bloodless apparatus,' and a Lister's aortic compress applied. The patient was laid upon his back, with the thigh flexed, and the incision commenced above the trochanter major with its convexity directed downwards, over the entire posterior surface of the upper part of the thigh, and terminating at the border of the inner surface of the thigh and perineum, at the origin of the adductors. The flap was separated as far as the tuber ischii. Next, the thigh being extended, the extremities of the flap were united by an oblique incision, immediately below the Poupart's ligament, which readily opened the articulation. So far the operation was bloodless; but, after the limb was removed, and the aortic compress probably shifted, the pubic, gluteal, and several small vessels spouted, and were immediately tied with catgut ligatures. The flaps were then brought into exact apposition, and a drainage-tube placed in the wound. The patient made a good recovery in about six weeks, and could bear a wooden leg.

Disarticulation of the thigh-bone has, since the American and Franco-Prussian war, somewhat fallen into disrepute. In Langenbeck's civil practice the results are not bad, since in four cases in which the operation has been performed for osteomyelitis or tumour of the thigh-bone, three lived; and in his communication of eight cases of disarticulation for gunshot injury (Berlin, 1868-9), only one survived. The Americans consider 'shock' to be the cause of the great mortality, as influenced by the removal of one-fifth part of the body, or the division of the great mass of nerves. Langenbeck denies this cause of shock, since it would be equally the same in civil practice, and considers that the cause lies in the fact of the great loss of blood.

In the campaigns of 1864 and 1866 all these operations were performed too late, and all turned out unfavourably, as they did in the late war.

PUBLIC HEALTH.

PROUST ON ANTHRACOSIS AMONG COPPER-WORKERS.—Dr. Proust recently brought forward this subject at the Académie de Médecine, in a treatise specially devoted to the study of this malady among moulders in copper or bronze.

The *Gazette Hebdomadaire*, in passing in review the work of previous observers of this malady, reminds us that accidents occasioned by the introduction of carbonic particles into the respiratory passages were referred to so long ago as 1813 by Pearson, in a paper read before the Royal Society of London: that in 1831 Gregory and Christison found in the lungs of a miner certain hollows or cavities, surrounded by a black substance, which they recognised to be coal. In 1837 Béhier found the same kind of lesions, proceeding from the same cause among workmen exposed to coally emanations. Later, in 1854, M. Tardieu devoted his special attention to anthracosis among workers or moulders in copper. Works upon the same subject were published by Kiembault, Bouillaud, Traube, Beaugrand, and others. The *Gazette Hebdomadaire* omits to notice Dr. Headlam Greenhow's important observations on the 'black-lung of miners.' Under the article 'Anthracosis' in the *Dictionnaire Encyclopédique des Sciences Médicales*, written by M. Dechambre, there is a complete history of this question, in which nearly all the works on this subject are summed up and criticised.

In Dr. Proust's recent treatise he proves primarily that the almost general substitution of fecula for coal-refuse will render less and less frequent this appearance of anthracosis among moulders in copper. It is, therefore, a disease which has a tendency to wear itself out, at least among artisans of that calling; but there are others, such as coal-heavers and miners, who must necessarily remain exposed to it.

As regards the manner in which the coally particles penetrate, M. Proust believes that it is effected solely by the alveoli or respiratory channels. The cells of the epithelium which line the alveoli, and the thin membrane which sustains them, are easily traversed by the particles of coal. These particles make their way into the conjunctive interalveolar tissue, where their accumulation speedily induces a conjunctive hyperplasia. The conjunctive tissue becomes softened, and cavities filled with a blackish pulp are formed in the pulmonary parenchyma. Most complete details of the progress, evolution, and symptomatology of this lesion, and the heart complaints which it engenders, will be found in the article 'Anthracosis,' to which we have already alluded.

At the last stage—at the time when the paren-

chyma thus forms for itself multifarious cavities—the disease puts on all the clinical appearances of pulmonary phthisis; at that stage only can it merit the name of carbonic or coal phthisis.

It is well known that it has been proposed to style by the name of 'professional phthises' a certain number of pulmonary complaints arising from the inhalation of various dusts or powders, observed more particularly among needle-makers, millstone-makers, stonecutters, carders, etc. For this denomination of phthisis, applicable only to the last period of the disease, M. Proust proposes to substitute that of 'pneumoconiosis,' introduced by Zenker. The disease in question might here take the name of anthracotic pneumoconiosis among moulders.

M. Proust promises to return to this question, and to speak especially of the clinical forms which the disease may assume. W. LOMAS, M.D.

OBSTETRICS AND GYNÆCOLOGY.

DEPAUL ON THE DIAGNOSIS AND TREATMENT OF PERITONEAL EXTRA-UTERINE PREGNANCY.—In the *Archives de Tocologie*, September, 1874, M. Depaul contributes an article on this subject. In four previous articles he has dilated more fully upon the signs and symptoms that diagnosticate this affection; and the various pathological conditions that exist with or without pregnancy, and certain isolated phenomena which complicate it at times. In spite, however, of the real difficulties arising from these pathological states, and in spite of the co-existence of isolated phenomena which occasionally complicate extra-uterine or uterine gestation, he believes that an almost certain diagnosis can be arrived at after the sixth month. In deciding, it is necessary to pass in review the particular conditions of the case; all are not equally favourable. Up to the end of the fourth or fifth months, the signs are those of uterine gestation; even if they differ in a few particulars, they are not incompatible with normal foetation, or are too slightly marked to attract attention. In the first place, it must be decided whether the woman is really pregnant. The foetal pulsations remove all doubt, and, later on, it gradually becomes apparent that the foetus is not *in utero*. The deviation of the cervix begins to be more and more marked, and its consistence is no longer in harmony with the period of gestation. The conformation of the tumour, which is by degrees drawn to one side of the abdominal cavity, does not present the usual appearance of a gravid uterus. The foetal parts are more superficial, and are surrounded with less liquor amnii. The head and breech often form two projections which stretch across the abdominal parietes, which are sensible to the sight or touch. The transverse diameter of the tumour is sometimes longer than the vertical. It is obliquely placed, and appears to be attached inferiorly to one or other of the iliac fossæ. The uterine souffle is relatively more rare than in normal pregnancy.

Nevertheless, all the above-named characters may be absent. The cyst may be ovoid, like the uterus; the liquor amnii may be as abundant as in the normal gravid uterus. In one case related by the writer in a previous article, there was dropsy of the amnion, which considerably increased the difficulties

of diagnosis; happily new symptoms showed themselves, which dissipated all doubts.

The foetus may live beyond the usual term of gestation, but as a rule it dies in the last two or three months. From whatever cause, the death of the child is shortly afterwards frequently signalled by symptoms which would lead to the belief that labour was near, but it does not occur. More or less acute pains arise in the abdomen and loins, often assuming the characters of expulsive pains.

It is incontestably true that the uterus often increases and takes part in the scene; there is a sanguineous discharge; the decidua, which is hypertrophied, is expelled in its entirety or in parts, as has been more than once proved by the microscope. M. Depaul is persuaded that this very commonly, if not constantly, occurs, though it has escaped the attention of most observers, from the *débris* being lost on the linen or mixed with clots. Occasionally the orifices of the uterus are half opened, so as to permit the introduction of the finger. In a case mentioned in a previous paper this was very marked. As a rule, however, the cervix presents an unusual position, and is reached with difficulty; and when felt, it does not correspond with the period of gestation. This peculiarity is one of the most important guides to diagnosis; should the cervix be very highly placed, and pushed either forwards or backwards, there should be no hesitation in introducing the hand into the vagina, to make out its exact condition, chloroforming the patient if requisite.

In the early stages, when all is uncertainty, the employment of the uterine sound is inapplicable; but later on, when the cessation of the action of the foetal heart shows the child to be dead, not much harm can accrue even if the pregnancy be intra-uterine. M. Tarnier prefers the finger; he gradually forces it into the cavity of the uterus, overcoming the resistance of the two orifices.

The kind of spurious labour mentioned above is of variable duration, and recurs one or more times. In the intervals the condition of the woman is far from being normal; there are fevers, rigors, and vomitings; the abdomen is painful in places. The pains have nothing in common with those which depend on uterine contraction; they are continuous, and are intensified by pressure of the hand; there is inflammation of the cyst, and they are the result of repeated peritonitis.

The breasts, which had exhibited the various degrees and modifications of pregnancy a few days after the death of the foetus, show signs of lactation; they swell, become hard, and milk escapes, sometimes in sufficient quantity to soil the articles of dress. The inflammatory symptoms which precede or generally follow very close upon the death of the child may be absent, but this is very rare. Sometimes, after having been repeated many times with a variable intensity, they subside, the general good health returning. The cyst remains more or less stationary a long time, gradually diminishing through absorption of the liquor amnii and mummification of the foetus, and may remain in the abdominal cavity without causing any mischief.

The writer relates a case to prove this, which happened in M. Guéniot's practice, where an extra-uterine pregnancy arrived at term, accompanied with symptoms simulating labour with inflammation of the cyst and death of the foetus, the woman making a complete recovery. Although there are several cases on record with a like termination, yet as a rule

the result is different, ending in the death of the woman, as in the following instance which came under the observation of M. Guéniot, where the pregnancy arrived at the full time, the foetus dying within ten days, and the mother at the end of the eleventh month of gestation. The cyst ruptured into the bowels, and the fluid was discharged *per anum* and by the mouth.

BIDDER ON A CASE OF HÆMATOMETRA IN UTERUS BICORNIS, WITH COMPLETE ABSENCE OF THE VAGINA; OPERATION; CURE.—Dr. A. Bidder, of Mannheim, describes this case in the *Berliner Klinische Wochenschrift* of November 16, 1874.

The patient was seventeen and a-half years old when seen; the family history was good, although she herself was slightly affected with rickets. At the age of sixteen and a-half she began to be every four weeks attacked with pains in the lower part of the abdomen, gradually increasing in intensity. At last in no position could she obtain relief, except when bent double. An examination of the genitals showed an entire absence of the vaginal orifice. From the orifice of the urethra to the posterior commissure was smooth, even mucous membrane with a shallow depression in the middle. With the finger introduced *per rectum*, the catheter in the bladder could be distinctly felt, only separated apparently by some loose cellular tissue. At the height of a little more than three inches from the anus an elastic body, in the site of the uterus, could be made out by conjoined examination; it was about the size of a man's fist, ovoid, elastic, and movable. No portion of the cervix could be felt. Of the diagnosis there could be no doubt; the difficulty was to open up a communication between the uterus and the closed vaginal orifice. The obliteration of the vagina was complete; was it, however, only by adhesion of the two surfaces as in union of the prepuce with the glans penis? or was it entirely absent? Cutting instruments were not applicable; blunt force alone could be used, and that, to be successful, must be in the direction of the axis of the pelvis, behind the urethral orifice.

The point of the forefinger was placed in the shallow depression; by working it backwards and forwards, and with a boring movement, it was possible gradually to separate the vaginal walls which had grown together. At places the finger slipped along easily, perhaps because the walls were here only adherent to one another.

There was slight hæmorrhage. At the depth of about three and a half inches the ovoid tumour was met with, and a space about 1·2 inches in diameter and projecting about four-fifths of an inch into this artificial vagina was opened out with the finger. There was no os to be found; at the most dependent part a hole was scratched with the finger nail, and a trocar was plunged in. What came away was thick, tenacious, coffee-brown liquid. The opening was enlarged with the finger. Care was taken not to press on or irritate the uterus for fear of stimulating it to contraction. The fluid was allowed to run away of its own accord. The vagina was syringed out with warm water. She made an excellent recovery, with only slight feverish symptoms on the eighth day. On account of an offensive mattery discharge, injections were employed for a few days. Menstruation took place without harm and in a moderate quantity.

Careful examination under chloroform was made, at a later date. The uterus was large, soft, and elastic; to the left and below the fundus was a thick prolonga-

tion about an inch and a half long, and half as broad, springing from the substance of the uterus, cylindrical in shape, and, in comparison with the rest of the uterus, hard; it was probably the other horn of an uterus bicornis; the supposition of an altered Fallopian tube or a neoplasm was not permissible. *Per rectum* no cervix could be made out, but from the inferior end of the uterus a small, cord-like nodular vagina. The finger could pass only about two centimètres up the vagina before it was arrested by a knotty structure; beyond this the uterine sound could be pushed as far as the shoulder. The finger, with force, could be passed about two-and-a-half centimètres further by tearing through the bands of connective tissue, it bled moderately. Laminaria-tents were attempted to be introduced to widen the upper part of the vagina. As far as the vagina was then dilated, an oiled tampon was inserted. On introducing the sound some weeks later, a quantity of offensive purulent fluid escaped, which for a time continued discharging. When last seen, at the end of nine months from the operation, the girl was quite well, and menstruated normally, and the vagina could now only admit the finger about half an inch; the sound, as formerly, passed readily. The uterus was as large as a goose's egg.

The author views this case as one worthy of notice, as a contribution to the causation of this affection, hæmatometra, which in this instance arose from a complete fusion and adhesion of the vagina along its whole length. Whether the projection from the side of the uterus was another horn, is not certain. In uterus bicornis (Veit, Virchow) one horn not unfrequently does not menstruate. The chief interest of this case is the successful creation of a vagina; unfortunately, the passage was not kept dilated with bougies, etc., and so soon contracted. The reason that the parts did not grow together again, arose, in the belief of Dr. Bidder, from the original firm adhesion being only an epithelial one; probably the remains of the epithelium grew again over the injured parts, forming a complete covering, permitting, however, contraction of the nodular connective tissue. The cause of the uterus remaining so large was not apparent. The author is under the conviction that the opening into the uterus was made opposite where the os should be, otherwise he thinks it would have grown together again. Finally, one does not always succeed in making a vagina by separating the fused parts. Lately, Professor Simon has proposed in these cases to dilate the urethra, and make a large opening between the uterus and bladder.

EBELL ON THREATENING SYMPTOMS FOLLOWING VAGINAL INJECTIONS.—In a paper read before the Society of Gynecology, in Berlin, on April 21, 1874 (*Berliner Klinische Wochenschrift*, September 21) Herr Ebell states that threatening symptoms (sudden pain, sickness, coldness of the extremities, faintness, etc.) similar to what is observed after catheterisation of the bladder or injections into the urethra, occur also after vaginal injections. Text-books do not regard it at all, and only few cases are related in journal-literature. These were given by him together with four instances that came under his own immediate observation. Of these four, three occurred in women with retroflexions, who had been confined six weeks, one year, and two years respectively. The fourth case happened in a woman with antelexion, who was delivered nine

months previously of an abortion, and had been treated two years before that with a sponge tent.

The medicated lotions were injected in each case by the women themselves by means of an enema-pump.

The symptoms passed off in every instance without further consequences. Concerning the etiology, the following features are to be regarded.

1. The women are very sensitive, and the too elevated or too reduced temperatures of the injections bear the blame.

2. Inflammatory collections in the neighbourhood of the uterus are irritated through stretching of the vagina (Voisin), or the diseased (carcinoma, Scanzoni) walls of the vagina become injured.

3. The fluid presses into the uterus, causing shock

4. There is such a thing as entry of air into the veins of the pregnant uterus (Olshausen, Depaul, Litzmann) or into a vaginal vein eroded by carcinoma (Stofella).

In the discussion that ensued, Dr. E. Martin stated that he believed that these phenomena, excepting under the above-mentioned quite exceptional circumstances, are not to be attributed to the vagina, but had to do with the entry of air or fluid into the uterus. He observed it once in a very anxious case, where from chronic fluor albus the uterus had got into a very relaxed condition. In this instance, most probably, a bent horn-tube was pushed up into the uterus. A second time he saw it after an injection in a pregnant woman, and death followed from entry of the air into the veins. The temperature of the injection was of importance. Bearing upon this point he had met with a case where a woman who had been confined fourteen days was seized with intense pain after each warm injection, whereas with water, at about 62.5° to 64.5° Fahr., no such pain was occasioned.

Herr Fasbender saw the above-described symptoms, with marked participation of the bladder, once after a vaginal injection in an antelexed sub-involute uterus, with the external os somewhat patent. Herr Ebell proposed to obviate the dangers suggested by Dr. E. Martin, by having only side openings to the vaginal tube of the irrigator.

CORRESPONDENCE.

RARE FORM OF HERNIAL STRANGULATION.

(To the Editor of the LONDON MEDICAL RECORD.)

SIR,—In the 'RECORD' of December 2, in the department of Surgery, there is a notice of a rare form of hernial strangulation by Dr. Kapteyn. Dr. Kapteyn says that he has not been able to meet with similar cases in literature. Nearly thirty years ago I published what seems to me a similar case in the *Edinburgh Medical Journal*, I think for August 1845, with remarks in which some similar cases are referred to. The case and comments will be found reprinted in Clinical Cases illustrative of the Treatment of Hernia, at page 1,402 of my *Lectures on Surgery*.

JAMES SPENCE.

MISCELLANY.

DRUNKARDS AND DIPSOMANIACS.—In a work recently published, entitled *Alcoholism, its various Forms, etc.*, Dr. Magnan defines the difference between alcoholism and dipsomania. Dipsomania he states to be a form of instinctive monomania; whilst alcoholism is a poisoning. He quotes Trélat, who says that 'drunkards are men who get drunk when they get the chance of drinking. Dipsomaniacs are people suffering from disease, who get drunk whenever they get an attack of their peculiar disorder.'

TRICHINOSIS IN GERMANY.—The *Magdeburg Gazette* announces that in the town of Linden 56 persons died of trichinosis. None of the victims were more than thirty-two years of age. The *Gazette* protests against 'the neglect of the sanitary service which might have saved 56 persons from a death, the occurrence of which is easily rendered impossible by a proper inspection of the food sold to the public. From the large amount of attention now paid to the subject of parasites and parasitic diseases at the English veterinary college, it is clear that this duty of inspection ought to be performed by skilled members of the profession.'

LIFE AND DEATH IN PARIS AND LONDON.—The municipal statistics of Paris just published show that from a population of 1,851,792, there were born in 1873, 55,905 children, 28,244 boys and 27,661 girls, being an average of 153 births a day, and a proportion of thirty children to every 1,000 of the inhabitants. London, of which the population (3,400,761) is not double that of Paris, shows more than a double amount of births in the same year. There were 41,732 deaths in Paris in 1873, comprising 21,380 males, and 20,352 females, being an average of 114 deaths daily, and a proportion of 22.54 to every 1,000 of the inhabitants. Here again London contrasts favourably with Paris; the number of deaths registered in 1873 having been only 76,634 in a population of more than double the amount of that of Paris.

PROPOSED CERTIFICATES IN STATE MEDICINE AT CAMBRIDGE.—The Cambridge Board of Medical Studies have reported to the Vice-Chancellor that they are of opinion that it is expedient for the University to establish examinations and grant certificates of competency in so much of State Medicine as is comprised in the functions of the officers of health. The certificate given to successful candidates should testify only to their competent knowledge of what is required for the duties of an officer of health. The Board recommend the following for the subjects of examination.—1. Physic and Chemistry. The principles of chemistry and methods of analysis, with especial reference to analyses (microscopical as well as chemical) of air and water; the Laws of Heat, and the principles of Pneumatics, Hydrostatics, and Hydraulics, with special reference to ventilation, water supply, drainage, construc-

tion of dwellings, and sanitary engineering in general. 2. Laws relating to Public Health. 3. Sanitary Statistics. 4. Origin, Propagation, Pathology, and Prevention of Epidemic and Infectious Diseases; effects of overcrowding, vitiated air, impure water, and bad or insufficient food; unhealthy occupations, and the diseases to which they give rise; water supply, and the disposal of sewage and refuse; nuisances injurious to health; distribution of diseases within the United Kingdom, and effects of soil, season, and climate.

THE PREVENTION OF SEA-SICKNESS.—Dr. Giraldès has published, in the last number of the *Journal de Thérapeutique*, an account of the means by which he avoided sea-sickness during two passages to England and back. He was at Boulogne last June en route for London, when the weather was so rough that many intending passengers hesitated to cross the channel. Dr. Giraldès was informed by a colleague at Boulogne that American physicians used the syrup of chloral as a preventive of sea-sickness with successful results. He therefore obtained some syrup of chloral, put himself into a quiet corner, and took his syrup directly the vessel was in motion, when, although his fellow-passengers experienced the usual unpleasant consequences, he arrived at Folkestone without having suffered the least inconvenience. The same results were obtained on the return voyage; but he increased the amount of chloral. He had again occasion to cross the channel at the end of September, by the night boat from Calais to Dover, and thinking with reason that the sea would be rougher at that season than usual; he had a draught made up composed of chloral, 3 grammes (45 grains); distilled water, 50 grammes; gooseberry syrup, 60 grammes; and French essence of peppermint, 2 drops. He took half of the draught as the vessel left the harbour, and arrived at Dover without having suffered in the least from sea-sickness, whilst his companions were in the usual condition of prostrate misery. A very heavy sea was running. On his return from London on October 30, there was a high sea and much wind; he accordingly took the remaining portion of his draught, soon went to sleep, and only awoke on his arrival at Calais in the best possible condition. Dr. Giraldès remarks that he is, as a rule, affected by sea-sickness when he crosses the Channel, and that his two trials of chloral have convinced him of its efficacy as a preventive of that most disagreeable malady. He adds that he never goes down into the cabin, but makes himself as comfortable as circumstances will allow on deck.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17s. 4d.; free by post, 19s. 6d.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & Co., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The First Volume, containing upwards of Two Thousand Articles abstracted and compiled by a staff of Fifty Hospital Surgeons and Physicians, is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for the year 1873 are also ready, price 1s. 6d. each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & Co.—Calcutta: THACKER, SPINK & Co.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & Co.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & Co., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, DECEMBER 16, 1874.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

ON DISEASE OF THE MAMMARY AREOLA PRECEDING CANCER OF THE MAMMARY GLAND BY SIR JAMES PAGET F.R.S.*

I believe it has not yet been published that certain chronic affections of the skin of the nipple and areola are very often succeeded by the formation of scirrhus cancer in the mammary gland. I have seen about fifteen cases in which this has happened, and the events were in all of them so similar that one description may suffice.

The patients were all women, various in age from forty to sixty years or more years, having in common nothing remarkable but their disease. In all of them the disease began as an eruption on the nipple and areola. In the majority it had the appearance of a florid, intensely red, raw surface, very finely granular, as if nearly the whole thickness of the epidermis were removed; like the surface of very acute diffuse eczema, or like that of an acute balanitis. From such a surface, on the whole or greater part of the nipple and areola, there was always copious, clear, yellowish, viscid exudation. The sensations were commonly tingling, itching, and burning, but the malady was never attended by disturbance of the general health. I have not seen this form of eruption extend beyond the areola, and only once have I seen it pass into a deeper ulceration of the skin after the manner of a rodent ulcer.

In some of the cases the eruption has presented the characters of an ordinary chronic eczema, with minute vesications, succeeded by soft, moist, yellowish scabs or scales, and constant viscid exudation. In some it has been like psoriasis, dry, with a few white scales slowly desquamating; and in both these forms, especially in the psoriasis, I have seen the eruption spreading far beyond the areola in widening circles, or, with scattered blotches of redness, covering nearly the whole breast.

I am not aware that in any of the cases which I have seen the eruption was different from what may be described as long-persistent eczema, or psoriasis, or by some other name, in treatises on diseases of the skin; and I believe that such cases sometimes occur on the breast, and after many months' duration are cured, or pass by, and are not followed by any other disease. But it has happened that in every case which I have been able to watch, cancer of the mammary gland has followed within at the most two years, and usually within one year. The eruption has resisted all the treatment, both local and general, that has been used, and has continued even after the affected part of the skin has been involved in the cancerous disease.

The formation of cancer has not in any case taken

place first in the diseased part of the skin; it has always been in the substance of the mammary gland, beneath or not far from the diseased skin, and always with a clear interval of apparently healthy tissue.

In the cancers themselves, I have seen in these cases nothing peculiar. They have been various in form; some acute, some chronic, the majority following an average course, and all tending to the same end; recurring if removed, affecting lymph-glands and distant parts, showing nothing which might not be written in the ordinary history of cancer of the breast.

The single noteworthy fact found in all these cases is that which I have stated in the first sentence, and I think it deserves careful study. For the sequence of cancer after the chronic skin-disease is so frequent that it may be suspected of being a consequence, and must be always feared, and may be sometimes almost certainly foretold. I believe that a nearly similar sequence of events may be observed in other parts. I have seen a persistent 'rawness' of the glans penis, like a long-enduring balanitis, followed after more than a year's duration by cancer of the substance of the glans. A chronic soreness or irritation (of whatever kind) on the surface of the lower lip often long precedes cancer in its substance; and, with a frequency surpassing all other cases of the kind, the superficial syphilitic diseases of the tongue are followed, and not superseded, by cancers which do not always appear to commence in a diseased part of the tongue.

For an explanation of these cases it may be suggested that a superficial disease induces in the structures beneath it, in the course of many months, such degeneracy as makes them apt to become the seats of cancer; and that this is chiefly likely to be observed in the cases of those structures which appear to be, naturally, most liable to cancer, as the mammary gland, the tongue, and the lower lip. One may suspect that similar surface-irritation has much to do with the frequency of cancer of the rectum, pylorus, and ileo-cæcal valve, in any of which parts the degeneracy, which might come naturally in old age, and make them apt for cancer, may be hastened and made prematurely sufficient by an adjacent disturbance of nutrition.

In practice, the question must be sometimes raised whether a part through whose disease or degeneracy cancer is very likely to be induced should not be removed. In the member of a family in which cancer has frequently occurred, and who is at or beyond middle age, the risk is certainly very great that such an eruption on the areola as I have described will be followed within a year or two by cancer of the breast. Should not, then, the whole diseased portion of skin be destroyed or removed as soon as it appears incurable by milder means? I have had this done in two cases, but, I think, too late. Or, again, when one with a marked family-liability to cancer has syphilitic disease of the mucous membrane of the tongue, with frequent recurrences of inflammation, should not all the worst pieces of the membrane be removed? I should certainly advise it, especially if the membrane were ichthyotic, if it were not that the disease is commonly so extensive that good scar-tissue would not be likely to be formed, and that bad scar-tissue, often irritable and ulcerating, is as likely to induce cancer as the syphilitic or ichthyotic patches would have been.

PICCININI ON THE SUCCESS OF SUBCUTANEOUS SYMPHYSEOTOMY IN CONTRACTED PELVIS.

Dr. Piccinini, of Cassano Magnago, Lombardy, writes in the *Lyon Médical*, October 25, 1874, as follows. Though symphyseotomy was born in France, it was soon abandoned there, and if modern text-books give it a place among obstetrical operations, it is only on account of its historical interest.

Professor Pietro d'Erchia (of Naples) attributes the rejection of this operation to three causes. The first is the accepted custom in France and England of always sacrificing the child for the safety of the mother; the next is the invention of Baudelocque's cephalotribe, which is superior to the hook of the English practitioners; and, lastly, the prevalence of induced premature labour, which permits us to avoid the disagreeable consequences of a pregnancy, by arresting it at any given moment.

It appears to me that, beside the causes mentioned by D'Erchia, there is another of greater importance; namely, the want of a definite rule to decide for the surgeon how much pelvic contraction indicates, and how much forbids, symphyseotomy, followed by the immediate application of the forceps. This is what has induced me to publish the ideas which guided me in this operation, which I performed with perfect success in May, 1870, saving both mother and child.

Symphyseotomy, in cases where the contraction had reached two inches and a half (about sixty-five millimètres), had given such bad results that it was soon abandoned. It was, therefore, important to fix precisely the degree of narrowing which permitted the operation, the moment at which it was indicated, and the immediate and subsequent precautions which should insure its success.

Symphyseotomy, that is the section of a fibro-cartilage, is, in itself, an equally harmless and simple operation. Joulin alleges that it is impossible, beforehand, to determine with perfect accuracy the amount of contraction and the volume of the foetal head, so that it might be necessary to follow the first operation with a second, to wit, the application of the forceps, and that this would add greatly to the danger of the former, and would be liable, according to him, to rupture the sacro-iliac ligaments. I do not hesitate to treat such allegations as absurd.

In the first place it is rare for a practitioner, with the many accurate instruments we now possess, to fail to determine exactly the amount of contraction. There is no reason to fear the application of the forceps, which, according to me, should follow every symphyseotomy, and I never have had occasion to deplore the accidents to which Joulin alludes. I pre-suppose, of course, that the forceps are applied by a skilful accoucheur. According to Joulin, symphyseotomy will permit the separation of the articular surfaces to the extent of from one inch to one inch and a half which he holds corresponds to merely one centimètre's increase of the antero-posterior diameter. Experience shows that this is not the case. Professor d'Erchia has performed symphyseotomy in a case of contraction to two and one-half inches (sixty-five millimètres), and according to me it should not be done where there is less than three inches (eighty millimètres) and with the forceps he delivered a living child immediately afterward. The mother survived this application of the forceps, which, according to Joulin, should cause death by tearing the sacro-iliac ligaments.

As for me, the results of my practice are sufficient data; the amount of space permitting the operation is from three to three and a half inches; after the operation, the forceps should be applied with care, and, by gentle traction and slight rotary movements, the child will be gradually delivered without further pain to the mother, or any traumatic complication. With a contraction to three inches, symphyseotomy will give an additional half inch, and the forceps as much more, making the antero-posterior diameter practically four inches, which is, certainly, a most satisfactory result.

Position of the Patient.—The woman should lie on her back, on a strongly inclined plane, the pelvis supported by a pretty hard cushion, and the head being the lowest part. It is clear that by this position the head of the foetus is prevented from pressing on the pubes, and the operation is thus facilitated.

Preparatory Catheterisation.—It is indispensable that the bladder should be empty during the operation; apart from the gain in the antero-posterior diameter, the bladder will be less exposed to injury from the instruments. It is well, after the evacuation of the urine, to depress the bladder with the point of the catheter, or, better still, to put it on one side, lest it should be caught under the arch of the pubes during delivery.

The Section of the Fibro-cartilage is to be performed by the subcutaneous method, according to the usual rules. The fold of skin may be made above the clitoris, and the best instrument is a slightly curved tenotomy knife, with a blade which must offer a certain amount of resistance.

A Bandage for the Body must be arranged beforehand, and, after the operation, moistened with a solution of gum, so as to make it immovable. Its object is to prevent any separation of the thighs, either by a movement of the patient, or by an accident on the part of those carrying her; indeed, she should not be moved till it is nearly dry. By the subcutaneous method, the suppuration is avoided which would otherwise increase the dangers. Another advantage is the suppression of sutures; for the soft parts, which by this method are spared, contribute greatly to holding the pubic surfaces in place.

To recapitulate, the conclusions of this paper are the following.

1. Never perform symphyseotomy when the pelvis is contracted to less than three or three and one-half inches (80 to 95 millimètres);
2. Operate by the subcutaneous method;
3. After section of the cartilage, apply the forceps;
4. The position of the patient, the previous catheterisation, the immovable bandage are details of great importance to the success of the operation.

To conclude, let me recall the statistics of symphyseotomy during five years at the hospital at Naples: operations, nineteen; women saved, fifteen; children saved, sixteen.

TOWNSEND ON SMALL-POX AND CHOLERA IN CENTRAL INDIA.*

On the character of the monsoon, whether it be long or short, whether the rainfall be scanty or abundant, mainly depend not only the supply of

* *Annual Report of the Sanitary Commissioner for the Central Provinces for 1873. Nagpur, 1874.*

food, but the prevalence and intensity of cholera, small-pox, fever, and bowel-complaints, the diseases which cause the greatest mortality. Though the rule is subject to variations, a period of five years will generally include both the rise and fall of a wave of epidemic small-pox over a wide country. The mortality from small-pox is by no means an unvarying measure of the prevalence of the disease. The number of deaths in a given number of cases varies greatly in different localities, and there is every reason to believe, that small-pox is a far more fatal disease in the Punjab and in the North-West Provinces, than in Southern India. One cause of this is, the higher proportion which the town population bears to the country population in the two first-named provinces; and small-pox is most fatal in towns.

Climate and season also exercise an important influence. In some years either the epidemic influence, or the causes that render individuals susceptible to its effects, are stronger than in others. The prevalence of small-pox in India is almost confined to the hot and dry season, and there is evidence that the mortality from it is aggravated in seasons of unusual drought.

Epidemics of small-pox, in spreading over the Central Provinces, apparently take a general course from west to east. It is remarkable, nevertheless, how, in almost all quarters, the principal town has been affected before the disease has spread over the district to any extent.

A marked fall of the mortality from small-pox in May may be generally taken as a sign, that the epidemic has exhausted itself and is dying out; but if on the other hand the mortality be greater in June than in May, though it will fall as the rains set in in July, and remain at a minimum in August and September, yet it will again rise rapidly as soon as the dry weather sets in. A difference in the fatality of the disease in different localities has been observed, and also in different seasons in the same localities. Thus, in the year 1874, the ratio of deaths per cent. to cases treated, has varied from a maximum of 24.9 to a minimum of 11.2, and in the same place from 17.1 in 1873 to 23.9 in 1874.

On the whole, vaccination may have helped somewhat to diminish mortality, but with respect to populations only partially protected by vaccination, it is almost impossible to estimate, how far a lower mortality is attributable to vaccination, and how far to other causes, as, the stage of the epidemic, and local conditions. Attempts to enforce vaccination, or the isolation of cases, when small-pox is prevalent, certainly lead to concealment of cases, and the apparent but not real effect, of what is called the stamping-out system of vaccination, is due to this cause.

There was little cholera in the Central Provinces in 1873, but some remarkable instances of the curious way in which cholera attacks travellers are recorded.

Dr. Wilmot left Jubbulpore, on August 9, on a visit to Mr. Jardine at Allahabad, returning to Jubbulpore on the morning of the 13th. Early on the 14th he was seized with cholera, and died on the following morning. When Dr. Wilmot left Allahabad, Mr. Jardine left for Mirzapore; he too was seized with cholera at that place, and died about the same time as Dr. Wilmot. On the day when Dr. Wilmot had premonitory symptoms, he was accompanied in the visit of some schools by Mr. Rogers. That gentle-

man went on a tour of inspection in the Saugor district, where there had been and was no cholera, and returned on September 2 to Jubbulpore, where also there had been no cholera, and went to reside in the hotel, which was near Dr. Wilmot's house. He was seized on the 13th and died. Another inmate of the hotel died two days afterwards, and a few more cases occurred in the station at irregular intervals. Dr. Townsend remarks, that the most probable explanation of Mr. Rogers's seizure is, that the infection had remained attached during the interval, to the clothes that Mr. Rogers had worn when with Dr. Wilmot, or to a box of office records, which Dr. Wilmot had made over to him on the 14th.

[The foregoing is a summary of the most important features of Dr. Townsend's careful report. The history of these remarkable cases of cholera, like that of many similar ones, has unfortunately been made out very partially; for instance, we are not told whether there was cholera in Allahabad, or along the road. A wonderful change of opinion has taken place of late years, when the commissioner at the same time talks of epidemic waves of small-pox, and holds extreme views as to the possibility of cholera contagion attaching itself to clothes or documents.—*Rep.*]

J. MACPHERSON, M.D.

GOLTZ AND FRENSBERG ON THE FUNCTIONS OF THE LUMBAR PORTION OF THE SPINAL CORD OF THE DOG.

Eckhardt concluded from the fact that erection could be produced by electrical stimulation of different parts of the brain, that the centre for erection lay in the brain. F. Goltz and A. Frensborg (*Pflüger's Archiv*, vol. viii., and abstract in *Centralblatt für die Medicinischen Wissenschaften*, no. 41) show, however, that in dogs, several days after section of the spinal cord at the limit between its lumbar and thoracic portions, by certain stimulations of different peripheric portions of the body erections occur reflexly, and this very regularly. If, however, the lumbar spinal cord be destroyed, erection does not take place. Just as the activity of other reflex centres can be inhibited by strong stimulation of the central ends of sensory nerves, so also is that of the lumbar centre for erection. Of course, this centre can be inhibited as well as excited through fibres which pass to it from parts higher in the spinal cord or from the brain. Thus is to be explained the fact that, after peripheral stimulation, erection does not occur so promptly in intact animals as in those with divided thoracic spinal cord; and on the other hand, the observation of Eckhardt and others, that erection follows stimulation of certain parts of the brain, is also explained.

According to the authors, there is also present in the lumbar spinal cord a reflex centre for the evacuation of the urinary bladder. For, when in dogs the spinal cord is destroyed at the limit between its lumbar and thoracic portions, gentle tickling of certain peripheral parts of the body produces evacuation of the urine.

The authors also believe that, even in the waking state in man, originally the activity of the bladder is excited not by the will, but reflexly from the mucous membrane of the bladder, whereby the first drop of urine enters the urethra. The further evacuation, however, can be continued afterwards by stronger innervation of the constrictor partis membranaceæ

urethræ. This centre also stands in connection with the brain through inhibitory and exciting fibres.

By analogous experiments, the authors show that the sphincter ani can also be excited reflexly to peculiar rhythmical activity, whilst the rectum exhibits peristaltic movements; and that the centre for these reflex acts also lies in the lumbar spinal cord.

Goltz showed, ten years ago, that in the frog the spinal cord exerts an influence on the tone of the blood-vessels. Legallois observed the same fact in rabbits, though he explained it incorrectly. The authors confirm the observation on the dogs on which they had experimented, that, immediately after section of the spinal cord, the hind feet become warm, but several days later, after the wound of the operation had quite healed, gradually the former tone returns. According to the authors, this can only occur under the influence of one or more centres placed in the lower part of the spinal cord, which become paralysed immediately after the operation, but gradually again become active. If the lumbar spinal cord be now again injured, an increase of temperature in the hind feet is again observed. After complete destruction of the lumbar spinal cord, the circulation is so affected that the animal dies. In a supplement, the author adds the remarkable fact, that section of the sciatic nerve in a dog also produces, in the leg supplied by it, increase of temperature, even when the spinal cord is completely destroyed.

In another communication on 'The Dilating Nerves of Vessels,' Goltz and Frensborg (*Pflüger's Archiv*, vol. ix.) deduce from their experiments:

1. The existence of local nervous mechanisms placed at the periphery, which govern the tonus and which regulate to a certain extent the blood-circulation;
2. The presence of vaso-dilator nerves in the sciatic nerve, which can be set in activity, either by simple section alone, and then by electrical and chemical stimulation.

These facts lead Goltz to regard the increase of temperature which follows section or stimulation of the nerves or of the spinal cord, not as a passive, or produced by paralysis of the nerves, but as an active phenomena.

Drs. F. Putzeys and F. Tarchanoff, at Goltz's request, undertook to investigate this subject (*Centralblatt*, no. 41).

A. The first point these authors investigated was: In what relation does the condition of the vessels stand to the temperature of the paralysed limbs?

1. When one sciatic nerve is divided in the thigh in a dog, and the toes of both hind-feet are then cut off, it is seen at once that the current of blood which flows out from the paralysed side is very considerable, whilst that on the sound side is very weak or scarcely present. The same result was obtained on young ducks and frogs. The same result was obtained in a frog on division of the roots of the sciatic nerve as they come out of the spinal cord.

2. On stimulating the peripheral ends of the nerves in these animals, the phenomena are completely reversed; the current of blood stops on the paralysed side, and becomes very obvious in the other. Stimulation with common salt gave the same result. These phenomena might be explained by the muscular contraction and tetanus in consequence of stimulation, but the same phenomena were observed in curarised dogs and frogs; however, in the frog, complete standstill of the outflow of blood did not take place. Direct observation of the vessels immediately after

the operation showed in the duck widening of the vessels; the blood was redder than in the sound foot. Stimulation of the nerves of the paralysed side caused narrowing of the vessels of this side. Microscopic examination shows that stimulation of the sciatic nerve after its section, either in the thigh or in the pelvis, a narrowing of the arteries, which may even go on to complete occlusion of the vessels, takes place.

3. If the stimulation be continued for several minutes as under 2, the narrowing disappears, and is followed by widening, which the authors regard as a phenomenon of exhaustion.

On stimulation of a part of the nerve lying more peripherally, the contraction of the vessels can be observed again.

B. 1. Section of the nerve in a dog yielded, just as in Goltz's experiments, considerable increase of the temperature in the corresponding extremity. When, however, the peripheral end was stimulated in a curarised dog, they did not obtain an increase, but a diminution of the temperature, which did not go so far that the paralysed side became as cool as the sound one, but still was 1.5° to 2° C. (2.7° to 3.6° Fahr.). In a duck the sinking was 2.5° C. (4.5° Fahr.).

2. The temperature of the paralysed side in dogs was found after three weeks to be the same as the sound side (corroborating Goltz). The widening of the vessels corresponds to the increase of temperature, and*the narrowing to sinking of the same.

C. On dividing the sciatic nerve in a frog, and cutting off the toes of both hind-feet, the blood flows out in greater quantity from the vessels of the paralysed side. After ten days, if a new section of the webs be made, blood drops out from both feet in about the same quantity. When, however, the spinal cord is divided in the middle of the back, or its lower part destroyed, it is observed that very little or no blood flows out of the paralysed foot, whilst from the other it flows out richly. After several days, the difference between the two sides has almost disappeared.

If the section of the spinal cord be repeated in this way, that always several days elapse between the individual operations, then a new increase of outflow of blood is observed from the leg, which still stands in nervous connection with the central organ.

These experiments support those of Goltz, and prove that a complete accordance exists between the conditions of filling of the vessels and the heat of the corresponding part of the body, and that the gradual return of the temperature to the normal is the consequence of the restitution of the tonus.

The authors derive the following conclusions from their experiments.

1. The restitution of the tonus of the vessels, which have lost their connection with the automatic centres placed in the brain and spinal cord, cannot be otherwise explained, as Goltz has already suggested, than by the existence of local peripheral arrangements, perhaps of a nervous nature, which they are not disinclined to compare to those which occur in the intestines; the tonus will therefore, in the first instance, depend upon this local mechanism, and secondly, upon the centres in the spinal cord.

2. The sciatic nerve contains vaso-motor fibres.

3. It is not yet proved that it contains also vaso-dilator fibres (after the meaning of Goltz), nerves which, according to the above authors, are unnecessary for the explanation of the different phenomena.

4. Section of the nerves and spinal cord produces, without doubt, a stimulation, whose effect is very evanescent, and which is followed almost immediately by paralysis.

5. The widening of the vessels and the increase of the temperature, which are sometimes observed immediately after the stimulations, are the effects of over-stimulation.

6. It might also be added that the vaso-motor fibres, after their section, are in a state of latent irritation, which, in consequence of an energetic stimulation, make way for exhaustion.

One does not therefore require the aid of vaso-dilator nerves to explain the increase of temperature which is observed after stimulation of a divided nerve, or of repeated division of the same.

WM. STIRLING, D.Sc., M.B. (Edinburgh).

ANATOMY AND PHYSIOLOGY.

ASP ON THE ANATOMY AND PHYSIOLOGY OF THE LIVER.—G. Asp (Ludwig's *Arbeiten*, vol. viii.), in his experiments on the secretion of bile, was led to make a histological examination of the liver of the rabbit, to ascertain why and how fluids excreted from the blood were divided between the lymphatics and bile-ducts.

The paper is divided into a histological and a physiological part.

1. Although it is well known that the nucleus of the hepatic cells is often double, still it is not a necessary part of these cells, and although, as is generally the case, it is present, it has not always the same appearance. The author has found that the nucleus may be absent from the hepatic cells, and has treated such a liver by all the methods at present known to histologists for this purpose, but has not been able to render a nucleus visible. This condition does not depend upon food having been previously withheld from the rabbit. Even in a piece of such a liver, which was placed for a long time in often changed 10 per cent. solution of common salt, no nucleus was observed. (The 10 per cent. solution of common salt is a very valuable isolating medium.)

The author also insists on the facility with which the hepatic cells are altered by pressure. Even under a pressure of 50 millimètres (2 inches) of mercury for injecting the portal vein, these cells assume the most varied and singular shapes.

With regard to the structure of the walls of the smaller bile-ducts, the author finds that, as long as the cylindrical epithelium is present, several layers of a striped tissue are visible between, by which, at regular intervals, numerous fusiform bodies are enclosed. The stripes and long axes of the spindles lie in the long axis of the ducts. These stripes disappear completely on boiling fine sections of the interlobular tissue in hydrochloric acid and alcohol (1 in 1,000). They thus conduct themselves differently from the middle layer of the small arteries, which is not affected by boiling in the alcohol and hydrochloric acid mixture. This fact supports the view that the stripes are composed of several layers of collagenous fibrillæ. The spindles have the appearance of nuclei. According to this view, the tissue surrounding the epithelium of the fine bile-ducts would belong to the layers of connective tissue (*Bindegewebshäuten*) which consist of fibrils and cells, so that the muscles which Heidenhain ascribes

to these ducts would be absent. Even if muscles are present they can only lie in the long axis of the ducts, for the spindle-shaped nuclei always run parallel to the duct. Asp recommends the injection of a 0.5 per cent. solution of chloride of palladium into the ductus communis choledochus, in order to obtain good preparations of the bile-ducts. The tissue is then placed for eight days in a concentrated solution of bichromate of potash. The cells are then easily brushed away, and the remaining stiff framework consists essentially of the interlobular tissue.

The bile-ducts, in penetrating into the lobule, lose at the same time their cylindrical epithelium and their striated investment, their walls being composed only of fusiform nucleated plates disposed in spirals. E. H. Weber has already shown that a solution of alkannine in turpentine penetrates into the interior of the cells, and the author has satisfied himself by the injections of gutta percha dissolved in alcohol, and afterwards by the non-passage of a watery solution of Berlin blue into the cells, that there is no rupture of the cells produced by the injections, and that therefore this passage of alkannine and gutta percha into these cells must take place by filtration. MacGillavry, as is known, injected intralobular perivascular spaces, both by injection of the lymphatics in the liver of a dog, and also by the 'puncture' (*Einstich*) method. Frey and Irminger confirmed the existence of these spaces for the liver of the rabbit. E. Hering, however, denied that these spaces were the origin of the lymphatics, and did not succeed in injecting them in the liver of the rabbit. Asp has succeeded in injecting them in the rabbit, by forcing serum for a long time into the vena portæ, under a pressure of 30 to 50 millimètres of mercury (1.2 to 2 inches).

2. Schmulewitsch, under Ludwig's direction, found that poisoning with curara slightly diminishes the secretion of bile. Asp corroborates this statement. From a series of experiments the author shows that a liver, from which the blood-current has been cut off for longer than ten minutes, can again form bile, when blood is admitted to it. If, however, blood be excluded for an hour or longer, then the secretion is only re-established in a very incomplete manner.

The condition of the secretion of bile was tested in a liver when the rapidity of the blood was diminished below the normal; first, by ligature of one branch of the vena portæ, whilst the corresponding branch of the hepatic artery remained open; secondly, by narrowing of the trunk of the vena portæ; and thirdly, by section of the spinal cord. The first of these methods was already employed by Schmulewitsch, who showed that the quantity of blood carried by the hepatic artery is sufficient for keeping up the secretion of bile, but this secretion by no means necessitates the properties of arterial blood, for it is known that the fluid flowing through the hepatic artery loses its bright red colour before it passes into the hepatic lobules, into the first capillary system. Closure or narrowing of the vena portæ and section of the spinal cord, diminished very materially the quantity of the biliary matter secreted. All these three conditions then diminish the secretion of bile. The injection into the jugular vein of a curarised rabbit of several quantities (30 to 40 centimètres) of a 0.75 per cent. solution of chloride of sodium, heated to 38° C. (100.4° Fahr.), did not exercise any notable influence on the biliary secretion. The quantity of solids in the bile, however, after

the injection of solution of common salt, showed a manifest diminution. These experiments, therefore, show that the blood can undergo very considerable changes in its composition without losing its bile-forming property.

The life of a rabbit could not be sustained by substitution of defibrinated dog's blood for its own blood. The cause of death the author believes to have been coagulations which were produced in the remainder of the rabbit's blood by the addition of that of the dog.

The author then attempted to establish a circulation of blood in a liver which had been excised from the body. This is a field which is likely to yield many new results; and already Professor Heger, of Brussels, under Ludwig's direction, has performed similar experiments on the excised lungs (*Artificial Circulation in Excised Organs*. P. Heger: Brussels, 1873). The liver of a rabbit was taken and kept at a temperature of 38° C. in an apparatus constructed for the purpose (we must refer to the original for details); and, as it was impossible to obtain the necessary amount of defibrinated rabbit's blood, the defibrinated blood of dogs, which had fasted for a considerable time, was employed and diluted with a solution of chloride of sodium, so that it could circulate in the vessels of the rabbit. This artificial circulation outside the body, and under as normal conditions as possible, was kept up for two to three hours, and a quantity of fluid, though a very small quantity, was obtained, which in all its properties, physiological and chemical, exactly resembled bile. The quantity obtained in the most favourable case was 0.5 centimètres, *i.e.* just as much as was obtained from the living liver in ten minutes with strong closure of the vena portæ. This bile is not derived from a store in the liver, for, if serum only be employed (at a pressure of 30 millimètres of mercury), bile is only excreted at the commencement; soon the liver secretes none at all, and if the pressure be much elevated (50 millimètres of mercury), the fluid excreted has not the properties of bile.

FLEISCHE ON THE LYMPH AND THE LYMPHATICS OF THE LIVER.—E. Fleische (*Berichte der Königl. Sächsischen Gesellschaft der Wissenschaften, Math.-Phys. Classe*, p. 42, 1874) says that if the lymphatics which proceed from the porta hepatis to the receptaculum chyli be exposed shortly after ligature of the ductus choledochus, it is observed that their usually colourless contents are tinged yellow. This formed the point of origin of the present investigation.

The supposition that the yellow colour exhibited by the liver-lymph was due to the admixture of bile, was confirmed by experiment. A few drops of the fluid gave distinctly with nitric acid Gmelin's reaction for the colouring matter of the bile. To ascertain whether it also contained the bile-acids, for special reasons (to be seen in the original) the lymph was not collected directly from the liver, but in a large curarised dog the ductus choledochus was ligatured through a small wound in the linea alba, and then the wound was sewn up. The thoracic duct was then exposed in the neck, and a cannula placed in it. In a few hours a sufficient quantity (100 to 200 cubic centimètres) of lymph was obtained. In about five hours afterwards, the dog was bled from both carotids. From this blood a completely clear serum was obtained by means of the centrifugal apparatus. The serum of the lymph

was also separated from the fibrinous clot which formed in it upon standing. The analyses showed that the lymph contained a considerable quantity of the bile-acids, whilst the blood did not contain a trace of them. The bile, therefore, when its natural outlets are occluded, passes into the lymphatics of the liver, and thence exclusively through the thoracic duct into the blood. If, in addition to the bile-duct, the thoracic duct be also ligatured, the bile does not pass at all into the blood, or only its traces.

The second part of the paper is devoted to the consideration of the question, what anatomical arrangement in the liver favours the passage of the bile into the lymphatics. In this part of the paper many new methods for the study of the structure of the liver are described.

1. All injections of the bile-ducts were made on the liver of the rabbit, before rigor mortis set in, and the pressure under which it was done was measured exactly. Alkarnin in turpentine was employed for the injection of the bile-ducts, and the red colouring matter, just as with Berlin blue, passed into the lymphatics. Many advantages over this mixture are offered by a filtered solution of asphalt in chloroform. For this mass, the pressure required is at least 30 millimètres (1.2 inch) of mercury. With this asphalt solution the author often succeeded in injecting from the bile-ducts not only the trunks of the lymphatics which run with the portal vein, but also the network which covers the diaphragm.

2. The author found that the lymph also leaves the liver by a channel other than those already known. In the connective tissue which binds together the strongest branches of the hepatic vein lie lymphatics, which empty their contents into those of the diaphragm.

3. The author then describes the connective tissue of the liver. For its preparations two methods were employed. A one per cent. solution of chloride of palladium was injected into the hepatic vein, and then the liver was hardened in bichromate of potash. The finest branches of the hepatic vein could then be easily isolated. The tissue forms a network composed of fibrillæ and enclosed cells; the meshes are about as long as they are broad. The smaller bundles of connective tissue cut the finer branches at right angles, so that the long axis of the meshes becomes increased. In the mesh-work of the larger fibres is a very fine network with exceedingly fine meshes. On this second network the hepatic cells sit fast. To obtain the very fine network which stretches from the adventitia of the hepatic vein, this vessel is washed out with a half per cent. solution of chloride of sodium, and then injected with a dilute solution of nitrate of silver. This preparation is treated similarly to the last, being first hardened, and then the hepatic cells are brushed away. The bile-ducts are then injected with a one per cent. solution of perosmic acid, under a pressure of 20 to 25 millimètres of mercury. Afterwards a watery solution of Berlin blue may be thrown into the bile-ducts, and the whole liver hardened in solution of bichromate of potash.

The very fine network of exceedingly delicate connective tissue which is brought into view by this process, seems to be a means of keeping the hepatic cells *in situ*. Its relation to the blood-capillaries has not been definitely made out.

From the perosmic acid preparations, the author believes that the bile-capillaries are by no means

mere furrows between the hepatic cells, but are independent structures with a proper wall. These bile-capillaries stand in no recognisable relation to the connective tissue.

WM. STIRLING, D.Sc., M.B. (Edinburgh).

SURGERY.

LEICHTENSTERN ON DIAPHRAGMATIC HERNIA.

The following case is interesting, not only as having been recognised during life by the rational and physical signs, but from the fact of a man so seriously afflicted having been regarded as a malingerer, thus fully confirming the views enunciated in vol. ii. of the *London Hospital Reports*, pp. 257-270, and especially the propositions, 'that nearly all those who feign diseases or accidents are in some way or other in ill-health; or in other words, that a basis of truth underlies most attempts at malingering;' and that 'in all cases of doubt it is better to assume for the time that the patient's statements are true, than to run the risk of maltreating or neglecting a real case of disease.'

The details of this case of diaphragmatic hernia will be found in the *Deutsche Klinik*, no. 29, for 1873, and the *Berliner Klinische Wochenschrift*, nos. 40, 41, 43, and 44 (Oct. 5 and Nov. 2, 1874); and the case is illustrated with woodcuts, showing the varying outlines of tympanic percussion, and the condition of parts *post mortem*.

The patient, Joseph Saile, a peasant, aged fifty-nine, was admitted into the medical wards at Tübingen, February 22, 1873, with the diagnosis of 'malingerer.' He said he could not swallow, that his windpipe had been 'ruptured' in consequence of a throttling he had undergone, and that he had 'the itch.' There was no proof of any of these things. His garrulity, proclivity to tears, and the long string of ailments of which he complained, gave the impression that his mind was affected. His most definite complaint was, that he was often suddenly attacked with dyspnoea, especially after eating, or defecation, after active exertions, and sometimes when quite quiet, and without warning. Examination of the patient disclosed slight cyanosis of the lips and prominent parts of the face, a short neck, the sterno-cleido-mastoidei being very much developed. Respiration was quickened. Both sides of the chest, seen from the front, were symmetrical. The respiratory type was mixed, but specially supracostal. The bones of the thorax were large. The percussion-sound over the liver was normal. There was epigastric pulsation. The apex of the heart was neither to be felt nor seen. Cardiac dulness was almost absent. With the exception of emphysema, the percussion and auscultation sounds were normal, except just under the inferior angle of the left scapula, where also the thoracic wall seemed more prominent. The percussion-note here was strikingly resonant and hollow ('full tympanic,' 'paste-board box tone,' or '*son creux*' of authors). Here vesicular breathing was quite absent, and was replaced by a metallic high-pitched sound in both inspiration and expiration, particularly in the former. Metallic tinkling and metallic succussion sounds were heard; and when the hammer of the plessimeter was used along with the stethoscope, beautiful metallic percussion-tones were brought out, at the same level as the metallic breathing. Dr. Leichtenstern soon discovered that the limits of this hollow space were constantly vary-

ing, and that they were affected by swallowing, and somewhat by changes of position. Combined auscultation and percussion were of the greatest service in definitely mapping out the extent of this 'cavity,' which afterwards proved to be chiefly 'stomach.' [The author writes as if combined auscultation and percussion were a novelty. Without discussing the vexed question of priority, which, the reporter believes, is justly claimed by Dr. Camman, it may not be amiss to note that it is mentioned in a common text-book (Barth and Roger's *Traité pratique d'Auscultation*, 2nde édition, p. 679). as long ago as 1844, with references to the American Medical Journals of 1840.—*Rep.*] He recommends the ulnar border of the little finger for estimating tactile vocal fremitus.

On June 2, 1873, it was noted that 'the whole left axillary region, and from this forwards with a snout-like outline in the cardiac region, as far as the left edge of the sternum, and upwards as high as the third rib, gave metallic resonance by auscultatory percussion;' whilst on the same day in the evening, vesicular breathing had not returned, nor vocal fremitus either, and the metallic sounds were nowhere. Besides this, a continuance of percussion often varied the pitch of the tones in a most striking manner, forming a musical gamut, just as happens in percussing the stomach, or an India-rubber bag, from which air can escape (*Deutsche Klinik*, 1873, p. 266), or from a glass plunged at varying depths into water. The physical signs present may be summarised as follows. 1. On the left, from below the inferior angle of the scapula, there lay a smooth-walled cavity, or hollow. [Metallic tones on auscultatory percussion.] 2. The position of this cavity was constantly changing. 3. This cavity, in a brief space of time, often changed, not only its position, but its form and volume. [This is strikingly shown in the diagram.] 4. The absence of vesicular breathing and vocal fremitus, when the metallic sounds vanished, showed that the lung did not replace the hollow space, although the latter, either from being filled in some way, or from contraction or irregular behaviour of its walls, no longer gave metallic sounds. 5. On the other hand, it was shown that the cavity sometimes partially retreated from the chest-wall, for at its upper and lateral borders it was sometimes replaced by lung (judging from physical signs). 6. It could sometimes be shown by the movable line of dulness, in different positions of the body, that the cavity was filled with mobile contents, and these limits of dulness, etc., were extremely variable. 7. The varying tones elicited forced to the conclusions that there was either one cavity with walls of varying thickness, or two or more cavities of different size. 8. Most curious of all was the fact that there were sometimes two or more quite separate spots giving the metallic sounds [shown by dotted lines in the diagram]. The sounds were less clear than in pneumothorax, and almost limited to inspiration, except as regards percussion. In pneumothorax, when extensive, the expiratory sounds are often loudest. Besides the symptoms just mentioned, there were bubble, borborygmi, and other intestinal sounds frequently heard over the thorax, just as they are heard in listening to the abdomen—and succussion-sounds—all of which were extremely variable as to times, and localities. These symptoms, regarded in their entirety, led to the conclusion that a diaphragmatic hernia must exist in this patient. He

was under observation three whole sessions. Dr. Leichtenstern discusses other proposed explanations of these phenomena, and shows them to be untenable. Further analysis of the physical signs showed that : 1. The opening in the diaphragm must be posterior ; as in the majority of such cases ; 2. It was almost certain that the stomach formed a part of the hernia ; 3. It was almost certain that other parts of the intestinal canal sometimes formed portions of the thoracic contents. The physical signs at various dates are minutely recorded, as well as experiments with swallowing, blowing air into the stomach, stomach-pump used both ways, etc. The patient swallowed quickly, and often large pieces, so that he was thought to be voracious. Dr. Wilks (*Lancet*, 1858) and Dr. Fraser (*Lancet*, 1856) draw attention to the inordinate thirst of patients who have intrathoracic ectopia of the stomach. Insufflation of air and clysters gradually led to the conviction that the colon also formed a part of the hernia. This condition of affairs appeared to date from a fall from a cherry-tree in 1870.

The diagnosis of his condition being thus established, and no further change occurring, he was allowed to return home, to light employment, on January 10, 1874. On the evening of May 11 of this year, after drinking about three pints of beer, and eating five-farthings' worth of black bread, he was attacked with extreme dyspnoea. Laden with tools, he hurried home, along an uphill road. He was seen to stagger, as if drunken, and on reaching his house, fell lifeless 'and discoloured' on the floor.

The *post mortem* examination was made two days later (May 13). On laying open the front of the body, the diaphragm on the right side reached the level of the sixth rib. On the left side it was much lower, and concave downwards. The cæcum and colon were much distended with gas. The former was dragged about a hand-breadth upwards from the iliac fossa, which was occupied by small intestine. The liver was pushed back forcibly. From the hepatic flexure the transverse-colon took its course upwards and to the left, and entered the thorax to the right and anterior side of a round opening in the diaphragm ; the portion of colon returning from the thorax lay below and to the left of this, and quickly terminated in the sigmoid flexure. When the transverse mesocolon was divided, and the epiploic sac was opened, the duodenum, greatly on the stretch, could be seen coming out of the opening, just behind the colon, running almost vertically upwards, and continuous with the jejunum ; by this stretching of the duodenum, the pancreas was raised into an almost vertical position, and rather more than an inch of its head projected into the thorax. The left hypochondrium, like the right, was filled with small intestine, and one coil occupied the thorax behind the colon. The spleen was adherent to the under border of the diaphragm, close to the opening. Neither stomach nor omentum could be found in the abdomen. The œsophagus, after passing through its proper opening, turned forwards in a sort of blunt hook-like curvature, embracing the posterior median edge of the opening in the diaphragm, thus returning into the thorax. On examining the thorax, the left lung was found to occupy only the upper half of the left chest, as low as the fourth rib. Below this lay the stomach, with its greater curvature anteriorly, in apposition with the thoracic wall ; thus its anterior wall lay to the right, above and posteriorly, whilst its posterior

wall was on the left in front and underneath. Its fundus lay to the left behind, partly on the vertebral column, partly on the upper surface of the diaphragm, to the left of the opening in the latter. The pylorus lay behind the lower part of the body of the sternum. The stomach was doubled almost in two within the left chest, so that the cardiac and pyloric ends were brought close together. [This is clearly shown in the diagram.] It was enormously distended, and held, besides much gas, nearly three pints of a brownish fluid with very large pieces of bread. The greater curvature measured thirty inches : and nearly two and a half inches of duodenum, ten and three-quarter inches of colon, with eleven inches of small intestine, and fatty omentum, flattened into a lump, occupied the left chest. The opening in the diaphragm lay partly in the muscular, partly in the tendinous portion, just in front of the œsophageal opening, severed from it by about one inch. It was quite round, with smooth, shiny, thick edges, as if corded ; there were one or two fatty fringes. Its diameter was three and a half inches, its circumference ten inches nearly. A medium-sized hand could be passed through it. There were no adhesions. All the dislocated parts could be easily returned into the abdomen. Even the left lung, though compressed, was free. The heart was firmly contracted in all its cavities, and quite empty of blood. [? Effect of agony.—*Rep.*]

The cause of death was apparently the enormous distension of the stomach, etc., hindering not only respiration, but circulation also, as shown by the heart and great vessels. [On this condition of heart reference is made to Sennert, on a case of hernia diaphragmatica, *Pract.* lib. ii. pars ii. cap. xv. ; also to Hildanus, *Cent.* ii. obs. 33, p. 108 ; Bonetus, *Sepulch.* lib. iv. sect. iii. obs. 21, sec. 3, 4, 5 ; Morgagni ; lib. iv. art. 11 ; and Beck, *Trans. Pathol. Society*, vol. vi. p. 220.] Dr. Leichtenstern speaks of the importance of recognising this condition in life, with a view to avoidance of undue exertion and regulation of diet ; and especially cautions against the use of emetics, which have proved fatal in numerous cases of the same kind. He discusses the means of treatment, if incarceration occur, naming the use of air and water-injections into the stomach and rectum, pumping out the stomach, exploring the rectum by the hand ; and if these fail, laparotomy (abdominal section) as recommended by Laennec and Kirschbaum, which he considers likely to succeed, the site of incarceration being known. He has collected 245 cases of diaphragmatic hernia, but reserves commenting for the present. Although Laennec in 1822, Dreifuss in 1829, and Bochdalek in 1848, had pointed out the probable utility of auscultatory and percussion-symptoms in forming a diagnosis of diaphragmatic hernia, it would appear that only four such cases have been really diagnosed during life—Olivet and Norris only suspecting their cases to be such. These four are Bowditch's (*Treatise on Hernia diaphragmatica*, Buffalo, 1853), Diego Coco's (*Virchow's Jahresberichte*, 1872), Lindwurm's (Popp in *Deutsche Zeitschrift für Chirurgie*, Von Hüter and Lücke, I. Bd.), and the one above described. The author considers left-sided diaphragmatic hernia six times as frequent as right-sided, from analysis of the 245 cases. [Notwithstanding the length of this abstract, many matters of interest have been omitted, simply from want of space. For the same reason, references to English cases are not inserted.—*Rep.*] W. BATHURST WOODMAN, M.D.

ANGER ON HETEROPLASTY.—In a recent note to the French Academy (*Comptes Rendus*, Nov. 23) the author says he has made some researches and clinical observations, as to transplantation of certain parts of the skin borrowed from amputated members and applied with the view of obtaining cicatrization in other subjects. The name of heteroplasty has been proposed for this operation.

In treating the case of a patient who had a large burn on the foot and leg, the author first sought to promote cicatrization by using epidermic autoplasmic grafts, as recommended by Reverdin; but as it seemed difficult to get a sufficient number from the subject himself, he tried grafts from the amputated members of other subjects, and succeeded. This first success led to his operating with dermo-epidermic grafts, obtained in the same way. He succeeded here also, and he then presumed he might advantageously transplant grafts comprising the whole thickness of the skin, and even the subcutaneous cellular tissue.

A first heteroplastic cutaneous graft was made with pieces comprising the whole thickness of the skin, taken from the palmar surface of an amputated finger. The grafts were $\frac{1}{2}$ to $\frac{3}{4}$ inch in circumference, and were applied to the ulcerated leg of another subject one or two minutes after amputation; they were held by strips of diachylon. Three days afterwards M. Anger removed the strips and found that the grafted parts were intimately united to the surface of the burn, and manifestly vascularised.

He also effected the grafting of portions of skin of entire thickness, which surrounded a tumour of the lumbar region; also the preputial mucous membrane of a young subject that was circumcised.

In all cases the graft was made with tissues that retained the temperature of the body. In the two last the subjects were placed near each other, so that the transplantation might be done without any loss of time.

Observation showed that the epidermis covering the grafted pieces became in a few days less adherent, and seemed about to fall off; which it actually did at the end of five or six days, leaving the piece denuded like the surface of a tegument newly recovered from a blister. The cicatrix, nevertheless, formed very rapidly over the whole surface of the piece and at its periphery. This result seems to warrant the belief that the grafts called epidermic only succeed on condition of a lamella of the dermis remaining united to the epidermis.

M. Anger remarks that he can anticipate numerous and fruitful applications of his method. The operations are always absolutely inoffensive, since the parts separated for other operations suffice. The surgeon should pay the greatest attention to the diathetic states which may have pre-existed in the subject from whom the tegument is removed. It would be very imprudent to perform heteroplasty with portions of skin taken from the direct neighbourhood of a cancerous tissue, or to operate with the tissues of a subject having contagious disease.

[There is nothing new in M. Anger's method. Freshly amputated limbs have been used as sources of skin for grafting by English surgeons for the last four years at least.]

JAGER ON NECROSIS OCCASIONED BY PHOSPHORUS.—The recognition of necrosis occasioned by phosphorus dates from about twenty years back.

Lorinser, of Vienna, was the first to describe this disease, which has since been much studied by many surgeons. The seat of the disease is generally in the maxillary bones, but it may extend thence to the bones of the face and the cranium. Dr. Jager has studied this complication and the resultant indications for its treatment, in a work entitled *Contribution à l'Étude de la Nécrose de Cause phosphorique*. He affirms that this extension of the disease is occasioned by the stagnation of the pus, which must be met by incisions and openings; and also by the expectant method, which, however, even up to the present time, has been too generally applied. The author then passes in review the opinions of different writers on the subject of phosphorus. Various surgeons are divided into two camps; some, like Lorinser, Trélat, Hervieux, and Nélaton, wishing to delegate to nature the task of accomplishing the work of separating the sequestra; while others, amongst whom may be named Langenbeck, Billroth, Jobert de Lamballe, Verneuil, and Guérin, advise intervention when the necrosis threatens to invade the whole of the bone, and also the resection of the necrosed parts before their removal. In support of the latter method, M. Jager states that the osteitis often continues its invading progress after the sequestrum is removed; besides which, the suppuration which accompanies the disease is a cause of exhaustion. Finally, when the pus does not flow freely and easily, it may loosen the periosteum and favour the progress of the osteitis.

This, however, is by no means an exhaustive theory. Every case, as M. Magitot remarks in the *Union Médicale* for 1873, offers particular conditions and different indications. This subject is worthy of the consideration of practitioners who find themselves in face of two methods of treatment of an entirely opposite nature, and who will do well to act according to the special conditions in which they find the local state, and the general condition of the patient.

EMMET ON HOT WATER INJECTIONS IN UTERINE DISEASES.—Dr. T. A. Emmet (*New York Medical Journal*, July, 1874) makes the following remarks upon hot water as a means of controlling pelvic circulation and imparting tone to the pelvic vessels.

The prolonged use of hot water is followed by a tonic contraction of the arterioles, and thus an approach to healthy action. The immediate effect of heat is dilatation, the secondary effect contraction. The best method of using hot water to obtain its contractile effect is as follows.

The woman is placed on her back, with the hips elevated by a properly shaped bed-pan under her, and a gallon or more of hot water at 98° Fahr. or a

higher temperature is slowly injected into the vagina by means of Davidson's syringe. This operation blanches the mucous membrane and diminishes the size of the canal, as if strong astringent had been used. While the hips are elevated the vagina will retain during the injection a large quantity of water, which, by its weight, will distend every portion of the canal, so that it will come into direct contact with the mucous membrane, under which the capillaries lie. The vessels of the neck and body of the uterus pass along the sulcus on each side of the vagina, and their branches encircle the canal in a most complex network. The vessels of the fundus, through the veins of which the blood passes by the liver back into the general circulation, communicate with those below by anastomosis.

We can thus, through the vagina, influence directly or indirectly the whole pelvic circulation. We can so diminish the supply as not only to check congestion, but we can literally starve out an inflammation. I know, says Dr. Emmet, from my own personal observation, that several of these injections a day at 100° to 106° will abort an attack of cellulitis if resorted to early enough, and their use persevered in, with the aid of rest and anodynes. These injections exercise a most beneficial effect on the reflex system, by allaying local irritation. I know no better means for removing the nervousness and sleeplessness of an hysterical woman, than a prolonged hot-water vaginal injection when administered by an experienced hand. The injections will frequently soothe a patient in less time than could be done by any drug in the *Pharmacopœia*. To receive permanent benefit from their use, they must be continued until the patient is restored to health. They should be given once a day, preferably at bed-time. The only position in which the patient can receive any benefit from them is on the back, with the hips elevated, as described. She cannot administer them properly herself—and I know no arrangement which can take the place of an intelligent nurse. As the patient improves in health, the quantity of water can be diminished and the temperature lowered, until the injections are discontinued from daily use, but for some time they should be employed for a few days after each period.

ROBIN ON THE PHYSIOLOGICAL AND THERAPEUTICAL ACTION OF JABORANDI.—At the meeting of the Paris Société de Thérapeutique, on November 11 (*Bulletin Général de Thérapeutique*, November 30), M. Robin gave an account of the result of researches made by him, and under his direction, on this new therapeutic agent, in M. Gubler's wards. When an infusion of four grammes (about one drachm) of jaborandi leaves is administered to an adult, the following changes take place in the urinary secretions. The quantity of urine diminishes in a very noticeable manner on the day the remedy is administered, but on the next day there is sometimes a slight augmentation, sometimes the usual amount. The urea undergoes the same modifications in quantity; it diminishes on the day the jaborandi is given, increases slightly again on the next day, and then falls to the normal amount, so that it may be asserted that jaborandi does not increase combustion of the animal economy. Chlorine and the chlorides, as well as the uric acid, also undergo the same quantitative changes, and diminish on the first day only to increase on the second. Examination of the saliva and the perspiration has not shown the

presence of uric acid, but urea is found in notable quantities in these two liquids.

In several cases of Bright's disease, jaborandi lowered the amount of albumen on the first day it was administered, but on the next day the quantity increased again, and sometimes exceeded the amount noted before the experiment.

In thirty-two experiments in which the temperature and the pulse were noted, it was observed that at the moment the sweat was produced, there was an increase of the pulse and of temperature; then during the period of active sweating, it was sometimes noted that these two elements remained at the same point as at the outset of the experiment. Sometimes there was a slight diminution; but after sweating, a very notable lowering of the pulse and of the temperature were observed, which sometimes lasted two days after the experiment.

Sphygmographic tracings, taken at different stages of the administration of this drug, showed almost complete asystolia with a very noticeable diminution of vascular tension during the sweating stage. M. Robin therefore thinks that jaborandi has a quite special action on the vaso-motor nerves, which are paralysed by it; hence the cardiac asystolia and the abundant secretions of saliva and sweat. When administered in fractional doses, jaborandi does not produce either perspiration or salivation, but becomes a powerful diuretic.

In the case of animals, as dogs and guinea-pigs, in addition to the salivation, an enormous secretion from all the intestinal glands was noted, accompanied by considerable congestion of the digestive canal, which might go on to hæmorrhage. M. Robin proposes to continue his researches, and to furnish the fresh results of them to the Société de Biologie.

M. Gubler said that, whilst admitting the paralyzing action of the vaso-motor nerves, which would increase the secretions and the excretions, a special irritant influence of certain elements of the jaborandi on the sudoral and salivary glands of the kidney must be allowed for, since this irritant action stimulated their secretory powers.

REGNAULT ON SUBCUTANEOUS INJECTIONS OF MORPHIA IN DYSPNŒA.—According to Dr. Alexander Regnault (*L'Union Médicale*, June 2, 9, and 18), subcutaneous injections of hydrochlorate of morphia are not only useful in relieving pain, but modify very effectually attacks of dyspnœa. This result is always obtained, whatever may be the cause of the breathlessness, whether it be owing to an affection of the thoracic organs or not—whether or not it be accompanied by pain.

The observations which Dr. Regnault brings forward to prove this statement are divided into two classes. In the first the result only is stated, without any mention of the cause. In the second the *modus agendi* is studied, and with this object, the pulse, the temperature, and the respiration, are carefully noted. In looking over the observations of the first series, it is at once seen that the number of inspirations is lessened soon after the injection of the morphia, and this decrease is entirely in accordance with the received ideas as to the action of opium and morphia. Opium diminishes the number of respirations; it is therefore hardly astonishing that an injection of hydrochlorate of morphia should successfully combat dyspnœa, arising from any cause whatever.

As the number of respirations decreases, the size

of the chest increases. The majority of patients treated for dyspnoea, were breathing quickly and noisily before the injection; ten minutes or a quarter of an hour afterwards their respiration was imperceptible to the ear, and on inspection the chest was seen to dilate slowly and regularly.

In support of the preceding statements, several observations, chosen from among the most striking contained in the work, may be quoted. In observation iii. of the second series, under the title of pulmonary phthisis, complicated with pneumonia, on June 27, 1872, the oppression was extreme, the number of respirations amounting to fifty per minute. Two injections of a solution (one part in 100) of hydrochlorate of morphia were administered. Ten minutes afterwards the patient was perfectly calm, and the number of respirations was reduced to twenty-three. In another case the result was the same. The patient, who was suffering from traumatic pneumonia, had, on the evening of May 13, a terrible attack of dyspnoea. The number of inspirations per minute was forty-eight; on the following morning it had fallen to thirty, and the patient felt quite comfortable.

The cessation of the dyspnoea cannot be attributed to any other than the medicine in question, for in some instances the result followed rapidly on the administration of the morphia, ten minutes having sufficed to produce a complete calm, and in one case the patient was quieted in from three to four minutes. The best preparation both for soothing pain and preventing dyspnoea is the hydrochlorate of morphia. Narceine, of which the effect is perhaps more certain, may be used, but the difficulty of obtaining this substance perfectly pure, and also its high price, is an obstacle to its employment. Injections of atropine should not be used on account of their danger and the serious accidents they have caused. The solutions of morphia generally used are of the strength of one in fifty or one in a hundred.

The concentrated solution is preferable, because in giving the same quantity of morphia in half the volume there is less chance of abscesses being formed where large doses have to be administered.

To obtain a certain and a rapid result, it is safer to inject into the walls of the thoracic cavity. This fact seems an argument in favour of the opinion held by some, that morphia has both a local and a general action.

The following conclusions may be drawn from Dr. Regnault's observations.

1. Injections of morphia seem to possess a real efficacy in cases of dyspnoea, whether it be a symptom of disease or a complication of it.

2. The decrease of the number of inspirations under the influence of the morphia explains the invariability of the result.

3. The effect produced is more certain and more rapid if the injections be made in the thoracic walls.

HUCHARD ON FEVER AND COLD BATHS.—A series of articles on the treatment of fever by cold baths has appeared in *L'Union Médicale*, in which M. Henri Huchard draws a parallel between the German (Brand's) and French methods, and asserts that in 1849 a French medical man, M. Wanner, communicated to the Académie des Sciences the advantageous results which he had obtained by the use of ice-cold enemata and lotions in typhoid fever. In 1849, another Frenchman, Dr. Jacquez (of Lure)

spoke highly of the good results obtained by the use of bandages, lotions, and enemata in the treatment of dothienenteritis; and in 1852, Dr. Leroy published the statistics of the results of Dr. Wanner's and his own treatment of typhoid fever. He found the mortality to be seven per cent.

Dr. Huchard makes the following observations.

1. It is certain that in typhoid fever the elevation of temperature through a relatively long period creates a serious danger, which we have considered sufficiently to make us hold very definite views on the subject.
2. Brand's method is difficult to carry out and often impracticable; the method of the French doctors, on the contrary, can be easily adapted to the constantly changing indications of the disease.
3. The two methods, which have a common aim, give results which are sensibly the same. In most cases we prefer the method of cold applications, lotions, and enemata. However, in cases where the temperature attains 41° or 41.5° C. (105.8° or 106.7° Fahr.), or rises higher; in cases where the temperature remains high for a lengthened period, and when the ataxo-dynamic phenomena are intense; and specially in cases of dothienenteritis where the danger arises from a hyperpyretic temperature or from predominance of grave ataxo-dynamic symptoms, Brand's method may be used with advantage; but it is in such cases only that it can be employed.

The French method is a combination of various means, which may be condensed into the following rules for application.

- a. Every two or three hours (according to the indications) cold lotions should be applied for the space of two or three minutes to the whole surface of the body. Dr. Wanner proposes continuing night and day the application of cold, by means of a brush to the affected parts. But M. Huchard prefers lotions applied with a large sponge; and Dr. Jaccoud recommends for the lotions the use of pure aromatic vinegar, which, he considers, has the triple advantage of producing a more intense and durable cold, of better exciting cutaneous hæmotosis, and of keeping up around the patient a scented atmosphere which revives him and maintains the purity of the air. The lotions are applied as quickly as possible with a large sponge to the whole surface of the body, and the patient is then immediately wrapped in a blanket to dry. This blanket should be placed on oil-skin, and should be passed under the body of the patient, who should be completely naked before applying the lotion. The temperature of the lotion may vary from 8° to 10° Cent. (46.5° to 50° Fahr.) according to the season and to the temperature of the patient. M. Jaccoud thinks that in winter the lotion should be at the temperature of the room, whilst in summer it should be kept in a cool place.

- b. Every two or three hours carefully alternating with the lotions, should be administered one or two enemata of water at 8° or 10° Cent. (46.5° to 50° Fahr.) and even, if the indications be urgent, at the temperature of melting ice.

- c. Bandages of cold water, renewed as they become heated, should be applied to the abdomen, the chest, and the head, according to the predominance of the abdominal, thoracic, or cerebral symptoms.

- d. The patient should drink nothing but ice-cold water, and that as frequently as possible.

BÉCHAMP ON THE PEROXYCHLORIDES OF IRON FROM A MEDICAL POINT OF VIEW.—After having shown that since his father's researches a series of

combinations from $\text{Fe}_2 \text{Cl}_3$, $\text{Fe}_2 \text{O}_3$, to $\text{Fe}_2 \text{Cl}_3$, $28 \text{ Fe}_2 \text{O}_3$, may be obtained by treating perfectly neutral perchloride of iron with varying quantities of peroxide of iron, M. Béchamp, junior (*Montpellier Médical*, 1874) indicates the octoferic peroxychloride as the best for internal use. This officinal peroxychloride is given in doses of from five to twenty drops.

The following are the conclusions at which M. Béchamp has arrived.

'The octoferic peroxychloride of iron is one of the compounds the most easily absorbed, as it is most readily transformed into compounds containing the minimum of iron.

'It is easily tolerated by the system, as it is neither caustic nor irritant, and it does not offer the disadvantages that many preparations of iron do. It is tasteless, and acts internally as a hæmostatic, in the same way as the perchloride of iron. It can be employed in surgery as a hæmostatic. It coagulates the blood in the same way as the perchloride of iron; but its power of coagulation and its causticity diminish with the base of the oxychloride. The surgeon has therefore at his disposal liquids decreasing gradually and uniformly in astringency and causticity. Finally, it may serve as an antidote in cases of poisoning by arsenic.'

GAUDIN ON THE THERAPEUTICAL INDICATIONS IN SEA-BATHING.—In a thesis on sea-bathing (*Thèses de Paris*, 1874) Dr. George Gaudin comes to the following conclusions. 1. From its elementary and chemical composition, sea-water is a revulsive agent, which accounts for the harmlessness of the vapour of sea-water. 2. A salt-water bath has no advantage over a cold fresh-water one, except that the reaction which follows it is increased by the stimulating action of the salt water on the integument. 3. There is no absorption by the skin of the principles contained in sea-water; and therefore its therapeutical results cannot be explained in that way; and further, the increase in the quantity of urine secreted is no proof of the absorption of water. 4. To sum up, we believe that the physiological and therapeutical results attendant upon sea-bathing are due to the revulsive properties of the sea-water, but still more to the sea-air. 5. Except in cases of respiratory and secretory anæmia, in cases of scrofula, of rachitis, and of some catarrhal pulmonary affections, sea-bathing offers no definite indications.

PUYGAUTHIER ON THE USE OF OXIDE OF ZINC IN THE TREATMENT OF DIARRHŒA.—From the results obtained by M. Gubler, Dr. Henry Puygauthier (*Thèses de Paris*, 1874) considers the oxide of zinc as the most prompt and effectual agent in cases of diarrhœa. Four grammes (about one drachm) of the oxide are given during the day, in doses of one gramme every two hours, in wafer-paper. In order to prevent the formation of salts of zinc, and the nausea and vomiting which would ensue, M. Gubler mixes four and a half grammes with fifty centigrammes of bicarbonate of soda, and has obtained with this mixture the best results. Administered in this way, the oxide of zinc loses its nauseating and emetic properties, whilst it retains all its power as an anti-diarrhœic.

R. SHEDLOCK.

posed the following as an excellent form for the administration of raw meat:

- R. Raw meat, ʒviii ;
Sweet almonds, ʒjss ;
Bitter almonds, ʒjss ;
White sugar, ʒijss .

The almonds are blanched, and the whole beaten together in a mortar until a rose-coloured homogeneous paste is obtained. This is of an agreeable flavour, and may be mixed with water to form an emulsion, or it may be beaten up with the yolks of eggs, and mixed with milk instead of water.

Mr. James Kemble, in the *American Journal of Pharmacy* for October, proposes the following very similar formula:

- R. Fresh raw beef (lean), ʒvj ;
Sweet almonds, deprived of their shells and roasted, ʒj ;
Bitter almonds, ʒvj ;
Sugar, ʒvj ;
Glycerin, ʒij ;
Water sufficient for emulsion, ʒj .

Rub or beat the beef, almonds, and sugar to a fine pulp in a wedgwood or wooden mortar, then add water gradually until a smooth emulsion is formed, and strain through a sieve or coarse cloth; return the residuary mass to the mortar, manipulate with the balance of the water until ʒxv are obtained, strain all through a finer strainer, add the glycerin, and bottle; the bottle is to be kept well corked. The dose is ʒj , containing ʒij of the beef.

The physician, in prescribing, can order the addition of brandy, pepsin, or any other medicine he wishes to administer at the same time.

WATSON ON THE USELESSNESS OF MERCURY IN SYPHILIS.—Dr. P. H. Watson takes a prominent place among the non-mercurialists. At a recent meeting of the Medico-Chirurgical Society of Edinburgh, he stated that his experience of the administration of mercury in syphilis was, that it did no good but a great deal of harm. Syphilis left untreated by anything except local applications got as certainly well as measles or any other exanthem. To give mercury in measles would hardly be deemed indispensable by any one at the present day, but it would be quite as rational as to give it in syphilis. No doubt, the early symptoms of syphilis disappeared rapidly under the use of mercury, but only to return again, unless the mercury were continued throughout the whole period of the eruptive tendency. Dr. Watson wondered how many of the strenuous advocates of mercurial treatment ever watched a case of syphilis when no treatment was allowed to complicate its natural progress. He was sure, if they did watch a few such cases, they would cease to employ mercurials. It was the opportunity afforded in watching cases under syphilisation which led him to these conclusions. He had no objection to mercurial applications to local lesions, such as the indurated chancres, or to condylomatous eruptions. The mercurial vapour-bath acted on this principle when no inhalation was practised, and, by its local effect upon the erupted surfaces, tended to hasten their disappearance. In cases of syphilis where mercury had been administered, serious so-called tertiary lesions did sometimes occur, and in these mercurials sometimes were required to overcome the evil results of their early administration. In such circumstances, he believed that the injection of the bichloride of mercury, as recommended by Dr. Duncan, might advantageously take the place of the use of

YVON AND KEMBLE ON EMULSION OF MEAT.—At a meeting of the Société d'Émulation pour la Science Pharmaceutique, (*Detroit Review of Medicine and Pharmacy*, October, 1874) M. Yvon pro-

mercury by the mouth, especially in cases where the stomach was rendered irritable by the use of the drug. The bichloride of mercury was best known to us in the shape of the toy called *serpents de Pharaon*. Possibly in the case of the injection of the bichloride in syphilis, this only needed a slight transposition of name to explain its action, behaving in the disposal of the germs of syphilis just as the redoubted *serpent de Moïse* in the instance of the magical imitations of the Egyptians.

Dr. Cadel said, he had seen mercury administered subcutaneously in Hamburg in 1868. In Christiania, Professor Boeck ridiculed the treatment. His own experience coincided with that of Dr. Watson, that mercury was unnecessary in syphilis.

OPHTHALMOLOGY AND OTOTOLOGY.

ILLING ON THE CAUSES OF HEMIOPIA.—In the *Allgemeine Wiener Medizinische Zeitung*, nos. 24, 25, and 26, Dr. Illing, assistant to Professor Stellwag von Carion, has recorded in great detail an interesting case of hemiopia, which is worthy of attention just now when the hitherto received and accepted notions with regard to the anatomy of the optic commissure have been challenged and controverted by anatomists of unimpeachable authority.

Lieutenant A. D. retired to his bed-room in good health on the evening of February 11, 1874; and, not knowing that there was any fire still burning in the stove, he closed the windows and the ventilator of the room. At twelve o'clock on the day following, the room was opened, and he was found insensible in his bed. After active restorative measures had been adopted, amongst others a powerful emetic, he was restored to consciousness at the end of three hours, but he appeared to be absolutely blind. In the course of the next few days, however, his sight returned to such an extent as to permit his seeing large objects as though through a fog, and his general condition improved, so that, with the help of a stick and with the arm of a comrade, he was able to leave his room. In the course of the next few days the indistinctness of vision increased, and he applied to Dr. Illing, who thus describes his condition.

Both pupils were of medium size, and sensitive to light; right eye, myopia = $\frac{1}{4}$; left eye, myopia = $\frac{1}{2}$. The central vision of the right eye was normal, but that of the left eye was below the standard. The optic disc in each eye was of a normal colour, but there was a myopic staphyloma around each, larger in the right than in the left eye; in the neighbourhood of the yellow spot in the left eye was a yellow-white patch of atrophied choroid, bordered with black pigment, the cause apparently of the defective central vision in this eye. There was no affection of the third pair, nor of the facial nerve, nor, indeed, of any cerebral nerve; his gait was unsteady, but there was no weakness of either half of the body. This unsteadiness was due to the fact that the patient, owing to his extreme myopia, had been accustomed, till his illness, to trust to very deep concave glasses,

but, having lately put them aside, he had been seriously at a loss to find his way about. He was, however, advised very strongly not to use his eyes in the least, and to be exceedingly moderate in his eating and drinking. His condition remained unchanged for some time. About the middle of March he found he had considerable difficulty in reading, and that if he removed the letters from his eyes to a greater distance, and especially if the words were long, he lost sight of the last part of them. He next observed that he could not see objects which lay to the right side, and he was very much astonished when it was demonstrated to him that even with his left eye he could not see anything which was situated to the right. He could see anything which fell within the inner half of the right visual field. Although he was very intelligent, and was constantly examining his own eyes, he was very hard to persuade that there was any defect in his left eye.

The extent and the shape of the field of vision in both eyes were mapped out with Förster's perimeter. That of the left eye was bounded by a line which extended upwards of 24° , and 20° to the right of the central cross, and 44° downwards; this line was not exactly parallel with the vertical meridian, but at its lower end formed a slight angle with it. From each extremity of this line the boundary of the field of vision stretched outwards so as to enclose a polygon. The boundary line of the visual field in the right eye passed exactly through the fixation point, upwards to a distance of 39° , and downwards 45° , slightly arched. The upper end of this line formed an exact right angle, and the lower end rather less than a right angle, as the boundary line turned inwards to enclose rather less than the usual extent of visual field on this side. Dr. Illing was much impressed in the examination of this case with the extreme value and handiness of Förster's perimeter, and he adds that he was extremely fortunate in having to deal with so intelligent a patient. The young officer had a firm idea that his right eye alone was in fault, and was very willing to give his physician very many sittings in which to repeat his investigations. Dr. Illing in all his measurements chose the centre of the blind spot as his point of fixation, and he ascertained that in the left eye this spot was 12° broad to the right of its centre, and 9° to the left. He also took the opportunity to ascertain if the increased breadth of this blind spot corresponded with the size and the shape of the posterior staphyloma; and he found, to his surprise, that although the staphyloma was nearly circular in shape, or, at least, resembled an ellipse with its long axis horizontal, yet the blind spot appeared like an ellipse with its long axis vertical, a discovery which agreed with the assertion of Heymann, made when he communicated to the Ophthalmological Congress at Heidelberg six years ago his new method of estimating the extent of the field of vision, to the effect that the elongation of the blind spot in the vertical diameter was due to the shadows which the central vessels, as they pass upwards and downwards, cast upon the retina.

It was extremely difficult to obtain an exact and sharply defined limit within which the hemiopia was confined; for after careful examination, aided by the intelligent co-operation of the patient, it was found that, on moving the object towards the boundaries of the field of vision, its colour was recognised some time before its shape and outlines were distinctly visible. In order to avoid, as far as might be, all possibility of error, the fixation-object was changed,

so as to check the measurements one with the other. The patient was ordered also to darken the eye, which was not under examination, by means of his hand, in order to avoid the narrowing of the palpebral aperture and consequent contraction of the visual field, which has been shown by Dobrowski to occur in a very appreciable degree. On the supposition that the optic commissure was undergoing pressure through an extravasation of blood, the patient took twenty grains of iodide of potassium daily for three weeks, and by the advice of some friends he underwent a course of electricity, but without any improvement in his condition, and, finally, in the month of May he returned to his military hospital.

The explanation of this case of hemiopia, from an anatomical point of view, rests upon one of two theories with regard to the arrangement of the nerve-fibres in the optic commissure. The first is based upon the recent observations of Michel* and of Mandelstamm, which go to show that the entire optic tract crosses its fellow at the commissure and passes into the optic nerve of the opposite side; and the other rests upon the long received opinion of Brown-Séquard and others, to the effect that each optic tract supplies fibres to each optic nerve, and that the inner fibres alone of each tract cross each other in the commissure. Dr. Illing believes that the peculiarities of the case which he records may best be explained upon the theory that the optic tracts completely cross one another, and by supposing the existence of an extravasation of blood within the angle of the commissure nearest to the left Sylvian fissures, and that the clot of blood compressed, though unequally, both optic tracts in such a manner as to injure the fibres, or some of them, which pass to the inner half of the left retina, and also to a greater extent those fibres which are distributed by the other optic tract and optic nerve to the outer half of the right retina. And as the defect in the visual field in the two eyes is so unequal, and as the two halves which retain their visual power cannot by experiment be made to combine so as to form one symmetrical perfect field, Dr. Illing does not see how to explain his case on the theory of the partial decussation of the nerve-fibres. He considers it very probable that the hæmorrhage, if there were any, was due to the violent sickness which resulted from the use of the emetics, as it is most unlikely that poisoning by noxious gas could occasion it. The patient before the present seizure was in perfect health, and there was no history of syphilis to occasion intracranial disease; nor any appearance or evidence of the existence of cerebral aneurism or of any other kind of tumour. As Dr. Illing remarks, the future progress of this case will be of great interest, and any further account which he may be able to obtain will be of considerable value.

ZEHENDER, LORING, AND MAGNUS ON THE DIAGNOSIS OF EMBOLISM OF THE ARTERIA CENTRALIS RETINÆ.—In this paper (*Klinische Monatsblätter für Augenheilkunde*, August-September, 1874) while he admits the admirable skill and cleverness with which the late Von Graefe laid down the ophthalmoscopic appearances which attend embolism of the central artery of the retina, Dr. Zehender yet inclines to believe that at the present

* Von Graefe's *Archiv*, Band xix. 2 Abth.

time there is a tendency to describe as instances of embolism certain cases which, while they resemble in many points the pictures which Von Graefe has sketched, are nevertheless wanting in one or more features of importance.

The phenomena which are usually said to betoken arterial embolism are sudden loss of sight, and a pallor of the termination of the optic nerve, with a narrowing or even obliteration of the arterial trunks; later on there is associated with these appearances a remarkable opacification of the retina in the neighbourhood of the yellow spot, and the subsequent appearance in this opacity of distended blood-vessels. It is the value of the latter change which Dr. Zehender calls in question; and in support of his disbelief he gives the details of a case which has lately occurred under his own observation; and to show that he is not alone in his mistrust of certain changes in the fundus being pathognomonic of embolism, he refers to the opinions of Loring and Magnus on the same point.

A countryman, aged twenty-one, without any exertion of any kind, and without being in any way able to account for it, became suddenly blind in the right eye, on the evening of April 25, and after an interval of four days he applied to Dr. Zehender. The vision of the left eye was perfect, and its refraction was normal. With the right eye he could but just discern the light of a candle at two inches; when it was held at a greater distance he could not see it at all; no reason whatever appeared for this sudden onset of blindness. On examination of the defective eye, the blood-red appearance of the fovea was distinctly seen, in contrast with the hazy appearance of the infiltrated retina in its neighbourhood; the vessels in this situation were evidently fuller than was natural, and more clearly seen; here and there a minute glistening yellowish white point could be seen in the immediate proximity to the fovea. The appearance of the fovea exactly tallied with the well-known illustration in Liebreich's atlas. The arterial branches, as they passed through the optic disk, appeared empty and bloodless; but the veins on the other hand were full, and as a remarkable fact there was a very decided venous pulse, the existence of which is an argument against the occurrence of embolism, inasmuch as its presence was an unerring witness to the continuance of the circulation. Two small veins which entered the disk on the temporal side were diminished in calibre. At the commencement of the attack, the man had suffered severe headache. On the eighth day afterwards two small hæmorrhagic spots to the inner side of the fovea were seen; by the twelfth day these had disappeared, and their place was occupied by small glistening specks, apparently containing crystals of stearine. In the course of time the veins dwindled, and the pulsation was no longer evident, and the case then assumed all the ordinary characteristics of arterial embolism. An examination at the hands of Professor Thierfelder demonstrated the existence of ventricular hypertrophy associated with insufficiency of the mitral valve; a loud systolic murmur was audible at the apex, and the second sound was muffled. The pulse at the wrist was somewhat later than the heart's systole. In reporting this case, Dr. Zehender asks whether it was really one of arterial embolism, or whether an extravasation of blood around and between the optic nerve-fibres would not give rise to similar phenomena.

In the *American Journal of Medical Sciences* for

April 1874, under the heading Remarks on Embolism, will be found an account of five cases which possessed, in a greater or less degree, the so-called characteristic features of embolism, and which had been diagnosed as being of that nature; but the narrator, Dr. Loring, thought that there was room for doubt as to the correctness of the diagnosis, inasmuch as he was at a loss to understand how the mere obstruction of the arterial trunk could occasion all the subsequent changes which the fundus of the eye is seen to undergo.

At page 319 of this number of the *Monatsblätter* will be seen a short review of a paper published on this same subject by Dr. Hugo Magnus; from which it appears that he too was unable to reconcile the appearances met with in these cases with the occurrence of embolism, but was disposed to consider them as the result of hæmorrhage into the sheath of the optic nerve, or between the fibres of the nerve itself. He considers that it is not impossible to diagnose between the two conditions, and he should look upon the peculiar infiltration of the retina around the yellow spot as the result of pressure on the nerve from hæmorrhage, rather than as the result of the arrest of the arterial supply. The absolute and sudden blindness, or the limitation of the visual field, will be of importance in forming an opinion of the seat of the lesion also. Magnus finds his opinions to be strengthened by the result of a series of experiments which he has carried out, in which he has both made injections into the sheath of the optic nerve, and has obstructed the circulation through the nerve by means of ligatures, and has then carefully noted the consequences. In the result, he is strongly of opinion that many of the so-called examples of embolism should in reality be looked upon as instances of hæmorrhage either within the sheath, or between and amongst the fibres of the optic nerve.

BOWATER J. VERNON.

MISCELLANY.

THE RIGHT MAN IN THE RIGHT PLACE.—The post of head apothecary to the Paris Assistance Publique, has been obtained by a gentleman possessing the appropriate cognomen of *M. L'Extrait*.

FEMALE MEDICAL STUDENTS IN RUSSIA.—It is announced that fourteen female medical students have just completed their course of study, under the direction of the Ladies' Committee of St. Petersburg, and will be passed in the present month after their full term of three years.

RECENT advices from Djeddah state that Dr. Pasqua, the sanitary inspector of the Red Sea districts, has been studying the nature and progress of the outbreak of plague at Beni-Chehir in that locality. He has convinced himself that the disease is the bubonic plague; but since the month of September, the attacks have been very few in number and limited to one village. It is believed that the measures adopted by Dr. Pasqua, and carried out under the surveillance of Dr. Agop-Effendi, will have the effect of stamping out the disease altogether.

A POLICY OF ABSTENTION.—The Medical School of Paris was partially re-opened after the late disturbances, on December 1. Two of the apparitors belonging to the school had orders only to allow fourth-year students to enter the room where M. Chauffard was to resume his interrupted course of lectures, and he commenced with an audience of thirty-nine. But after the lapse of a few minutes the students departed one by one until, according to the *Progrès Médical*, M. Chauffard had only three left to listen to his doubtless carefully prepared discourse.

DR. J. W. HICKS has been elected to a Fellowship at Sidney Sussex College, Cambridge. Dr. Hicks was Senior in the Natural Science Tripos, and third among the Senior Optimes in 1870. He for some time held the Lectureship in Botany at St. Thomas's Hospital, and is now Demonstrator of Chemistry in the Cambridge University Laboratory.

ADULTERATION OF SCAMMONY.—We learn that a large trade has hitherto existed between Aleppo and England in extract of scammony; but we are told that comparatively little is now exported. 'On account of its mixture with other substances,' only twenty cases in all, weighing 2,100 lbs., were shipped during the past year, the value of which was 1,680*l.*, and the whole of this came to England. In the previous year, 737 cases were exported, showing that adulteration alone is rapidly driving this article out of the import market, for the roots are produced as abundantly as ever, and are dug up and sent to England, the extract being procured from them in this country; in 1873 467 cases, weighing 93,340 lbs., and valued at 362*l.*, were shipped from Aleppo to England. Considering the bulk and weight of the root, as compared with that of the extract and the consequent increase of the cost of freight, it would seem that this exportation of the roots themselves can scarcely be a profitable trade to the shippers, inasmuch as 467 cases are valued only at 362*l.*, while twenty cases of the extract are worth 1,680*l.*

EMISSION OF CARBONIC ACID BY LEAVES.—The phenomena of decomposition of carbonic acid by leaves under the influence of light is well known. The inverse phenomenon, that, viz., of absorption of oxygen, and emission of carbonic acid in the dark, has attracted much less attention. MM. Deherain and Moisson have just communicated to the Paris Academy an interesting memoir on the subject. They find from experiment that the quantity of carbonic acid emitted by leaves is comparable to that furnished by cold-blooded animals; frogs give, in respiration, a quantity of the gas much below that from leaves of tobacco, or mustard, or sorrel. The quantity that leaves emit increases with rise of temperature, and at 59° Fahr. (it is stated) the respiratory activity of silkworms is comparable to that of decayed leaves observed at 86° Fahr., but considerably higher than what these manifest at 59° to 68° Fahr. Leaves kept in the dark, moreover, absorb more oxygen than they emit carbonic acid, and they continue to emit carbonic acid in an atmosphere deprived of oxygen. When carbon burns and gives carbonic acid, a certain quantity of heat is brought into play, and that heat is utilised, according to MM. Deherain and Moisson, for the formation of vegetal matter necessary to the growth of the plant.

M. LASÈGUE ON THE THERAPEUTIC USE OF WARM BATHS.—M. Lasègue thus summarises the rules which should regulate the administration of warm baths, in the *Archives Générales de Médecine* for Nov. 1874. He says that no one should remain in a warm bath longer than from twenty to thirty minutes at the utmost. The temperature of the bath at the time of getting into it should be lower than when the patient leaves it, whatever may be the degree of heat attained. The increase of the temperature should be gradual and regular. The best maximum heat is 48° Cent. (118.4° Fahr.), but 45° Cent. (113° Fahr.), is that most generally used. This degree of heat is easily tolerated if precautions be taken to avoid the sensations produced on the portions of the body not immersed in the bath, by the vaporisation of the water, and the maximum degree of heat be not kept up above eight or ten minutes. It is highly advisable to give as careful directions for the administration of baths, when personal superintendence cannot be given, as for the administration of any other therapeutic means; and the following formula should be filled up: 'Both time and temperature at the beginning . . . ; temperature at the end. Increase . . . degrees every five minutes. The bath to be repeated every . . . during . . . weeks.' When

the patient comes out of the bath he should be put to bed, and he soon regains, not his true temperature, which has not varied much, but his apparent temperature, which may be summed up in this fact—he should not be aware whether he is cold or warm. Generally a passing perspiration comes on, which must not be encouraged. It is best to leave the patient alone and not to interfere either to prolong or to abridge the effects of the bath by artificial means. M. Lasègue has applied these hot baths administered in this way to the treatment of chronic rheumatism going on to deformity, and the excellent results he has obtained from this treatment induce him to believe that the temperature plays an important part in the medicated baths recommended for this disorder.

THE HAMPSTEAD HOSPITAL QUESTION.—It is always satisfactory when unenlightened selfishness receives a check, and so we heartily congratulate Mr. Sclater Booth, and still more the inhabitants of north London, on the wise and firm tone of his reply to the Hampstead deputation, who desired to deprive the sick poor of the metropolis of one of their most needed asylums. The means of early isolation of patients stricken with fever is one of the most urgent necessities of every community. It is more directly and immediately the great need of the poor. For the fever-patient in the poor man's home is in immediate contact with all the family, and becomes a burning focus of disease, from which contagion radiates far and wide. Indirectly, the rich are considered not very much less than the poor, for fever which is housed in the home of the workman or workwoman spreads in innumerable channels of daily service to the homes of the rich. The opposition to the Hampstead site was unsupported by a title of evidence which could have weight with an impartial and judicial observer. It is an excellent site, sufficiently isolated, and within close range of the districts it is intended to serve. A tolerably extended experience has shown that a fever-hospital, instead of being a source of danger to the district in which it stands, lightens the fever-rate of that district. This was the experience of the surrounding district of the London Fever Hospital in the Liverpool Road. The explanation is not far to seek. The means of isolation being near at hand, the cases of fever are more promptly removed from the crowded rooms where they become sources of wide-spread infection. Hampstead Heath will not suffer, unless it be from the effect of the ill-advised slander, and the burlesque horror of the placards by which the party, whom the deputation represented, have sought to identify the heath with 'typhoid-fever,' and to make a death's head its emblem.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17*s.* 4*d.*; free by post, 19*s.* 6*d.*

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2*s.* 6*d.* each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & CO., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The First Volume, containing upwards of Two Thousand Articles abstracted and compiled by a staff of Fifty Hospital Surgeons and Physicians, is now ready, price 19*s.* 6*d.* Cloth Cases for binding the Numbers for the year 1873 are also ready, price 1*s.* 6*d.* each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & CO.—Calcutta: THACKER, SPINK & CO.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & CO.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & CO., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, DECEMBER 23, 1874.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

ON THE PARALYSIS OF CHILDREN ACQUIRED DURING DELIVERY. BY DR. SEELIGMÜLLER, OF HALLE.*

The form of paralysis which is here treated of was, as far as I know, first described by Duchenne de Boulogne (*De l'Électrisation localisée*, 3^{ème} édition. Paris, 1872) and is classified by him in a special group under the head of 'Paralysies Obstétricales Infantiles,' (*inter partum paralysis*). The number of recorded cases, as far as I have been able to ascertain, is very small, and not in accordance with the relative frequency of the disease, which, from the experience of Duchenne, and the statement of Professor R. Volkmann, is by no means rare. In textbooks and works on nervous affections, facial paralysis is only mentioned, arising from the pressure of the blade of the forceps on the trunk or branches of the facial nerve.

This paralysis is frequently enough seen, but is also frequently overlooked, as it is only perceptible when the child cries; and in most instances it ceases spontaneously during the first days of delivery without leaving any trace. Its pathogeny is very simple; the blade of the forceps presses on the trunk of the facial nerve or one of its branches, and causes an arrest in the excitability of the affected nerve-fibres, and consequent paralysis of the facial muscles supplied by them. That it is not always the whole facial nerve, but sometimes only one of its branches that is affected, is shown in a case observed in the lying-in clinic in Halle, and related by J. Cieslewicz in an inaugural dissertation (Halle, 1870). A child was delivered by the forceps, the pressure of the blade of which caused gangrene over the right angle of the lower jaw. The child exhibited facial paralysis of the right side, limited, however, to a few branches, those supplying the levator labii superioris alæque nasi, the levator anguli oris, and the zygomatici. Corresponding with this partial facial paralysis, the mark of the blade was found at the angle of the lower jaw, and not, as is usual, at the external ear, where the trunk of the facial nerve makes its exit.

Paralysis, in all cases produced in this way, can only be on one side, as the other blade of the forceps is applied over the frontal bone.

As has been already stated, these paralyses generally recover spontaneously during the first few days of infant life. In the cases quoted by Cieslewicz, one recovered by the third day and another by the sixth day; in a case cited from Osiander, recovery did not take place until the end of three months. In many of these cases, however, the paralysis is

permanent. Among others, Duchenne relates one which happened in a little girl of five and a half years, another in a girl of fifteen years; both of whom at those ages suffered from well-marked facial hemiplegia, which were notoriously produced by the forceps. In both instances the medical attendant and relatives had in vain waited for spontaneous recovery. When the patients were brought to Dr. Duchenne, all chance of cure by electricity was lost. The application of the forceps may produce, besides facial paralysis, paralyses in other nerve regions; e.g. paralysis of one or other of the upper extremities through pressure of the apex of the blade of the forceps on the brachial plexus. Of cases belonging to this form, the one most carefully observed, and consequently the most complete, is that of Dangau (*Bulletin de la Société de Chirurgie*, tome ii.). An eclamptic primipara was delivered by forceps, with moderate difficulty, of an apparently dead child, in which Dangau, thirty-six hours after delivery, observed facial paralysis of the left side, and at the same time motor paralysis of the left upper extremity. On the left side of the neck there was a nearly linear abrasion about 0.4 inch in length, along the outer border of the trapezius, produced by the right blade of the forceps; which in this way had injured the brachial plexus, and at the same time compressed the facial nerve at its exit from the stylo-mastoid foramen. The child died eight days after birth.

Guéniot (*ibid.* 1867) met with a very similar case. The facial paralysis, however, was absent. Twenty days after birth a slight improvement was perceptible in certain movements—the movement of the fore-arm upon the upper-arm; but the paralysis of the deltoid continued. The child was then lost sight of.

A third case was observed in Depaul's clinic. A primipara was delivered by the long forceps of an apparently dead child, considerable force being used. On the right side of the neck, where the neck and breast meet, at the anterior border of the trapezius, there was a blue abraded mark about 0.4 inch across, caused by the right blade of the forceps. When the child was eleven days old, the mother noticed that it never moved its right arm. The limb lay immovable along the trunk of the child; the fore-arm was extended, in a state of pronation; the fingers were flexed on the palm; these, as also the hand in a less degree, moved with fair freedom. The arm was completely powerless; if raised, it fell down like a lifeless mass; if the fore-arm were flexed, it immediately fell back to its former position. The contrast with the left arm was very striking. The sensibility of the paralysed arm was not at all diminished. If the skin were pricked or pinched, the entire right shoulder could be seen to move; only the arm remained inert, the upper arm, however, more so than the fore-arm, the latter exhibiting some imperfect movements. The shoulder was in nowise disfigured, showed no alteration in form, and was as lowly set as the other. The arm was not larger than the other; there were no signs of luxation, fracture, or contusion. There was certainly a complete outside and quite localised paralysis of the arm. The deltoid was entirely paralysed, the other muscles of the upper arm partially so. By the twenty-fourth day after delivery, after friction with warm aromatic wine, there was some improvement, the fore-arm could be flexed more, and the fingers were more movable. The

* *Berliner Klinische Wochenschrift*, October 5 and 12, 1874.

child was not seen later (*Journal für Kinderkrankheiten*, 1867, Band xlix.)

The case of bilateral paralysis, mentioned by Duchenne and others as observed by Smellie, I have not been able to discover in that author's works. More frequently, however, paralysis of one or both upper extremities is the result of difficult extraction, particularly in breech-presentations; in cases, therefore, where there has been some severe pressure and dragging on the shoulders. In these instances, in which often the whole strength of the accoucheur is employed, the pressure of the hooked finger, or of the blunt hook, may entail severe bruising of the trunks of the brachial plexus; and in the same way a strong and continuous pull on the shoulders may produce excessive stretching or laceration of the nerves or muscles.

Paralysis arising in this way may be accompanied with fractures or luxations in the region of the upper extremity. These complications are undoubtedly, in many instances, altogether overlooked, especially when they are not brought for medical examination until a long time after their origin. Even in quite recent cases, it is frequently only the practised hand of a surgeon that can diagnose these injuries. They may consist of detachment of the epiphyses of the scapula, or of the humerus at one or the other end; also of fractures of the clavicle, of the upper arm, of the scapula, and that not only of the neck but also of its body (see Case no. 5); finally, of luxation of the head of the humerus, of the sternal end of the clavicle, or of one of the bones of the fore-arm (Case no. 4.) These injuries may either occur singly or in a variety of combinations in the same individual (Case 2).

Respecting the pathological anatomy of the injured soft parts, nerves and muscles, I can find only one necropsy published, viz., that of the above-mentioned case by Dangau. In this instance there was found a slight extravasation of blood into the tissue surrounding the left brachial plexus at its origin. The nerve-fibres forming the plexus from their origin to beyond the scaleni were stained with blood, which was not removable by washing; their consistence was, however, normal. The facial nerve was similarly affected at its exit from the skull, and the surrounding tissues were ecchymosed.

Quite in accordance with this state of things is a communication in writing from Dr. Fritsch. In several necropsies made on breech-cases, he found in the neighbourhood of the shoulder numerous ecchymoses beneath the skin, and conjectured that the same had occurred in the region of the muscles and nerves. That such ecchymoses can alone produce paralysis of the nerves, so that with the disappearance of the extravasation the paralysis also vanishes, the following observation of Dr. Fritsch goes to prove. On the second day after a difficult delivery of the head, he discovered in the neighbourhood of the lower end of the sterno-mastoid a distinct baggy swelling (hæmatoma) about two inches broad. The arm was paralysed. With the complete disappearance of the swelling perfect movement returned. In this case, the paralysis appeared to be entirely dependent upon the pressure of the extravasated blood on the brachial plexus.

We will now more minutely describe the uncomplicated paralysees of the upper extremities. In the majority of cases, the attitude and the functional disturbances are the same. The typical form in nearly all cases is the following. The paralysed arm hangs

down motionless by the side of the trunk; in chronic cases, where the deltoid is already much atrophied and elongated, it is like a closely hung doll's arm. The head of the humerus is rotated inwards to its extreme extent; the triceps being thrown forwards. The position of the hand is most striking; it is in a state of excessive pronation, the arm lying along the side of the body, with the palm of the hand looking outwards; and in the most usual position of the arm, that of moderate flexion at the elbow, the radial border of the hand with the thumb does not look forwards and upwards, but the ulnar border, with the little finger, assumes that position. The function of the hand is, in consequence, much interfered with, although, as not unfrequently is the case, the fingers retain their freedom of movement. If a riding-whip, for instance, be placed in the hands of the child, it is held firmly; but, while the handle is held by the radial border of the hand, the whip-end and lash looks sideways and upwards from the ulnar border, and any movement of striking with the whip is evidently impossible. The active seizure of an object with the paralysed arm is impeded; if directed to lay hold of a stick, the child first fixes the object with his second hand, and then places it in the crippled hand. This maximum rotation of the head of the humerus, with its enforced abnormal position of the hand, may persist throughout life, and reduce to a minimum the use of the hand, even when there is complete power of movement in its individual parts. (Case 2).

The abnormal rotation of the upper arm depends entirely upon paralysis of the infraspinatus muscle, and therefore of the suprascapular nerve that supplies it. The infraspinatus alone rotates the arm outwards; consequently, when it becomes paralysed, its powerful antagonist, especially the pectoralis major, and also the subscapularis and latissimus dorsi, rotate the arm inwards. That the infraspinatus is really paralysed, has been conclusively proved by faradisation. The paralysis of this muscle during parturition may, as occurs in most cases, arise from pressure on its supplying nerve (suprascapular), or from direct pressure on the muscle itself. Other muscles in the region of the shoulder may be paralysed; for instance, the deltoid, and also not unfrequently the biceps and brachialis anticus. From the wasting of the deltoid, the head of the humerus sinks downwards, and a hollow appears beneath the acromion; while, in consequence of the paralysis of the flexor muscles, the arm becomes incapable of active flexion at the elbows. In the paralysed group of muscles, faradic excitability is more or less diminished or entirely disappears, sometimes soon after birth, sometimes, as in Case 1, four weeks afterwards. The sensibility of the skin appears generally to be retained.

As regards *inter partum* paralysees of the upper limbs, which are complicated with fractures and luxations, there are cases which at a superficial glance are not distinguishable from the above depicted uncomplicated ones. This is the case where the complications are trivial, such as detachments of the epiphyses, and such like. A severe complication may modify to a considerable extent the above-described typical configuration of the limb. Fractures not unfrequently cause shortening of the hollow bones, as the clavicle and humerus, or an arrest of their growth, or permanent deformities or alterations in position, as in Case 5. The rotation inwards of the humerus is favoured by fracture of the clavicle, Case 1. In Case 4, the luxation of the head of the

radius inwards contributed not a little to the deformity of the fore-arm and the functional incapacity of the hand. In cases where motor paralysis is accompanied by various and severe complications, the sensibility seems generally to be considerably affected. In Case 4 both fore-arms and hands were affected, particularly the left, and in a still higher degree in Case 2, where at the ninth month after birth there appeared to be marked anæsthesia of the fore-arm and hand. I have not, myself, met with a case of luxation of the head of the humerus into the axilla; but, from analogy with what is met with in adults, it may be said that pressure on the brachial plexus would produce paralysis of the arm. Duchenne observed in four children paralysis of the upper extremity complicated with subacromial luxation. Delivery in three cases was difficult, and in all four either the finger or the blunt hook had been inserted into the arm-pit. There was difficult or restricted elevation of the arm, the hand was prone, and the whole arm was rotated inwards; all movements in the opposite direction were difficult or impossible.

Besides those disturbances produced by abnormal positions of the head of the humerus, there are some which have been produced by lesion of the brachial plexus, and in which various muscles have been deprived of their faradic contractility and atrophied.

Smellie gives several cases in his work, *Cases and Observations in Midwifery*, where a persistent paralysis of the arm arose from luxation *inter partum*.

As to the prognosis, it has been proved experimentally, that the younger the animal is the more rapid is the reproduction of the wounded nerve. This experience may indeed be transferred from animals to men; but whether it affords any consolation in the case of *inter partum* paralysed children is another question. In the latter we have to deal not only with lesions of nerves, but likewise with lesions of muscles, and further still, of pressure upon the nerve-trunks from extravasations, etc. Consequently, the restoration of the injured nerve alone in nowise secures recovery from a traumatic paralysis. To leave to nature alone the cure of an *inter partum* paralysis, where there was probably a contusion of the nerves, would be very foolish. My own experience leads me to concur with the opinion of Duchenne, that if left alone, the paralysed muscles rapidly atrophy and degenerate. It is only the earliest possible application of methodical faradisation that can prevent this unfortunate result. In this lies the treatment of *inter partum* paralysis. Even facial paralysis should not be left to spontaneous recovery more than four weeks; and paralysis of the upper extremities a still less time. As soon as a child is five, or at the most six weeks old, a weak current of faradic electricity should be applied for about five minutes, twice or three times a week at first, to each paralysed muscle. Special attention must be paid to the infraspinatus muscle in cases of rotation of the head of the humerus inwards; both electrodes must be directly applied upon the fossa infraspinata. Passive rotation outward of the humerus should never be omitted. At first it seems to give much pain to the infant; later on, to please it. By this means, in the only case (Case 5) brought to me at the proper time for faradisation, a very satisfactory result was obtained.

In conclusion, I will observe that *inter partum* paralyses of the extremities may occur without any fractures or luxations. I am, however, acquainted with only one case of the kind (*L'Union Médicale*, no.

11, 1871) when the child lived to the next day. A primipara was confined of an apparently dead child, on whose feet the midwife had exerted such strong traction, that the necropsy showed complete laceration of the spinal cord and of its membranes had taken place in the region of the sixth and seventh cervical vertebræ. During life the upper extremities showed diminished sensibility and peculiar movements; and the lower, when the child was lying, were quite paralysed.

W. C. GRIGG, M.D.

(To be continued.)

CANTIERI ON THE PHYSIOLOGICAL ACTION OF CANTHARIDES.

Dr. Cantieri, clinical assistant and lecturer on special pathology in the University of Siena, has published in *Lo Sperimentale* for July, August, September, and October, an elaborate article, embodying the results of numerous experiments on the physiological action of cantharides. In the experiments he used various preparations, viz., tincture of cantharides, blistering plaster, and cantharidine. These were used sometimes in poisonous, sometimes in medicinal doses; in some cases they were brought into immediate contact with the blood, and in others with the tissues; and the effects were thus sometimes directly and sometimes indirectly produced. The experiments, which were carried out with the able assistance of Dr. Pico Cantucci, were performed on rabbits, dogs, and frogs; and a number of interesting details are given with regard to the effect of experiments of the following kinds:

Application of cantharides plaster to the axilla of rabbits, the skin having been removed:

Injection of tincture of cantharides into the blood-vessels of rabbits and dogs:

Subcutaneous injection of tincture of cantharides in frogs and in rabbits:

Subcutaneous application of cantharidine in rabbits and frogs:

Application of blisters to the belly of rabbits:

Internal administration of cantharidine and tincture of cantharides to frogs:

Injection of tincture of cantharides into the hearts of rabbits.

Dr. Cantieri gives each form of experiment in detail, and describes and comments on the results obtained; we can, however, only give his general conclusions, which are as follows.

1. Cantharides, when introduced into the animal organism, produces changes in the mass of the blood; it destroys and corrugates the red corpuscles when brought into direct contact with them, but only corrugates them when it reaches them by absorption.

2. It diminishes the contractile force of the heart and blood-vessels, and thus reduces arterial tension; it increases the frequency and the rapidity of the beats of the heart, increases the temperature of the body, and leads to wasting and general debility—all phenomena indicating the existence of a true and special fever.

3. Cantharides induces hyperæmia and stasis in various organs: and, if applied in a large dose, true inflammation. In the course of his experiments, Dr. Cantieri met with hyperæmia of the cerebrum and of the spinal cord; in the former, softening was slight; in the latter, it reached an advanced stage, being greater in the dorsal and lumbar enlargements,

especially the latter. Hence arose paralysis of the posterior limbs in dogs, in rabbits, and in frogs; and in the last-named animals, reflex power was also lost.

4. Hyperæmia of the membranes of the nervous centres, produced by cantharides, is always well marked at the base of the skull in the situation of the medulla oblongata, whence probably arise, in rabbits and in dogs, great frequency of respiration, and increased rapidity of circulation with occasional intermittence.

5. Cantharides always induces hyperæmia, or even true inflammation of the uropoietic and genital apparatus; giving rise to desquamation or parenchymatous nephritis, sometimes with albumen in the urine. It stimulates the sexual orgasm, and may produce abortion.

6. Cantharides administered internally produces, besides the morbid conditions already mentioned, a true gastro-enteritis, with extreme redness and ulceration of the mucous membrane of the stomach, and yellow mucous diarrhœal discharges. Occasionally, even when injected into the veins, if it do not produce ulceration, it occasions hyperæmia of the gastro-intestinal mucous membrane and frequent diarrhœa in dogs, frogs, and rabbits.

Dr. Cantieri then proceeds to comment on the medicinal application of cantharides, as a revulsive and rubefacient. We will give his views on this subject in a succeeding number. A. HENRY, M.D.

(To be continued.)

ANATOMY AND PHYSIOLOGY.

CARVILLE ON THE PHYSIOLOGICAL EFFECTS OF JABORANDI.—At the meeting of the Biological Society of Paris on November 28, M. Carville communicated the results of some experiments on the action of jaborandi, made by him in M. Vulpian's laboratory.

These experiments were made from a purely physiological point of view, with the intention of studying the mechanism of salivary hypersecretion in the submaxillary gland in dogs. The facts noted up to the present time show that an injection of twenty cubic centimètres (a little more than five drachms) of water, in which two grammes (thirty grains) of jaborandi leaves had been infused, into the crural vein of a dog which had had curara administered to it, and then been submitted to artificial respiration, brought on an excessively copious secretion of saliva, in less than a quarter of an hour. By means of a cannula inserted into Wharton's duct, the saliva may be collected both before and after the injection, during a quarter of an hour; and it was found that this secretion increased to four cubic centimètres under the influence of jaborandi; the saliva likewise becoming thick, thready, and opalescent. A subcutaneous injection of five centigrammes of atropine immediately stops this secretion. Division of the lingual nerve, and of its branches going to the submaxillary gland, has no effect whatever on the action of jaborandi on this gland.

Jaborandi has an analogous action on the urinary excretion; a cannula placed in one of the ureters shows that this excretion was increased in the proportion of from one to two cubic centimètres.

Experiment has also demonstrated that intravenous injection of water in the same proportion has

no influence whatever on the salivary secretion. From four to five hundred grammes are required to obtain a very temporary and trifling increase of salivation. In fine, the experiments hitherto made show that the action of jaborandi on the submaxillary gland of the dog does not affect the vaso-motor systems.

M. Carville proposes in further researches to resolve the question, whether this action takes effect on the peripheric extremity of the nerves of the gland, or on the secretory elements of that organ. M. Bernard drew attention to the fact that the conclusion to be drawn from M. Carville's experiments would be, that jaborandi does not act on the secretory nerve of the submaxillary gland. It may, however, act on the sympathetic nerves, inasmuch as the salivation observed after section of the cord of the tympanum was, in M. Carville's experiments, exactly like that produced by cervical sympathy. M. Bernard has shown that the saliva in these cases is viscid and rather copious, and M. Carville has found these characteristics present in his experiments.

M. Rabuteau remarked that he inclines to believe that jaborandi does not act on the nervous system, but on the striped muscular fibres. In the case noted, it must have been the muscles of the arterioles which were paralysed, since there are no striped fibres in any other part of the parotid gland.

PICARD ON IRON IN THE SYSTEM.—In a note to the French Academy (*Comptes Rendus*, Nov. 30), M. Picard says he has begun to study the variation of substances in the blood. He takes up the case of iron; and first, the limits within which it varies. The animals were chiefly dogs; and in some cases, when the blood was taken, they were in an indeterminate condition; in others, conditions were experimentally produced, in order to exaggerate the phenomena. All the animals were without food on the day of analysis; and the analysis was made on defibrinated blood. The following numbers show the quantity of iron per 100 cubic centimètres of blood in several cases; young, very fat dog, 0.092; adult dog, 0.065; another, 0.0565; dog weakened by previous bleedings, 0.041. These give the extremes; and it appears that the iron in a dog's blood may vary from one to two or even more.

Another question was, what is the signification of these variations? Guided by facts previously known, the author compared, in two specimens of the same blood, the quantity of iron per 100 cubic centimètres of blood, with the quantity of oxygen which 100 cubic centimètres, saturated with this gas, liberated *in vacuo*; the measure, as he calls it, of the respiratory capacity of the blood. It appears, from his table, that these two quantities vary in a parallel manner, and that their relation is sensibly constant, and equal to 2.3. This is equivalent to saying that the iron sensibly measures the respiratory capacity of the blood. (Here are some of the numbers: Iron, 0.090, 0.067, 0.048; oxygen, 0.0397, 0.0268, 0.0213.)

Thirdly, he inquired whether there was not an organ which might be regarded as a place of reserve for iron; and after examining several glandular organs, he found the spleen to contain, under ordinary conditions, a much higher proportion of iron than that in the blood. Thus the iron for 100 cubic centimètres of spleen is represented as follows: Dog, 0.24; dog, 0.22; ox, 0.15; cat, 0.34. In the liver, which, next to the spleen, contained most iron, the

proportion never exceeds that in the blood, and is rarely equal to it. (These researches were conducted in M. Cl. Bernard's laboratory.)

WEISKE AND WILDT ON THE FORMATION OF FAT IN THE ANIMAL BODY.—Voit and Pettenkofer have shown that in the dog, the body fat arises from the albumen taken in the food, and even when this is free from fat the carbohydrates take no part in the formation of the fat. H. Weiske and G. Wildt (*Zeitschrift für Biologie*, 1874, vol. x.; abstract in *Centralblatt für die Medicinischen Wissenschaften*, no. 43) treat the same question in herbivora, i.e., omnivora. For this purpose, two swine, from three to six weeks old, were killed, and the proportion of fat in the whole body was estimated, whilst another was fed for half a year on starch and potatoes. The food was weighed exactly each time, and often analysed; the faeces were collected, and by their analysis it was ascertained how much food had been absorbed. It was shown that the food was almost completely digested. We can only cite the results. The 'potato-sow' contained at the end of the experiment 2,2835 kilogrammes of albumen, 7,0138 kilogrammes of fat, 0,4101 kilogrammes of substances free from albumen. The control-animal, which at the beginning of the experiment may be regarded as of the same composition as the animal experimented on, contained 1,014 kilogrammes of albumen, 0,874 kilogrammes of fat, 0,0843 kilogrammes of substances free from nitrogen. There were thus formed during the feeding 1,2425 kilogrammes of albumen, 6,1398 kilogrammes of fat, 0,3258 kilogrammes of substances free from nitrogen; 0,5748 kilogrammes of fat were taken with the food. If we assume that this was directly absorbed, then 5,565 kilogrammes of fat have been formed in the body. The albumen taken in was 14,3244 kilogrammes; of this 1,2425 kilogrammes were stored up, so that 13,0819 kilogrammes remain disposable for the formation of fat. According to Henneberg, this could yield 6,7241 kilogrammes of fat. Thus, even with food very poor in albumen, the albumen taken in would suffice to explain the formation of fat, though, of course, the idea that the carbohydrates might have aided in the formation of fat is not excluded.

ADAMIEWICZ ON THE PHYSICAL PROPERTIES OF MUSCULAR SUBSTANCE.—Albert Adamiewicz, after a large number of experiments, concludes that the muscles of the trunk play a very important rôle with regard to animal heat. This is due to their physical properties.

1. Muscular substance is an exceedingly bad conductor. It conducts heat worse than water. The weak capability of conduction of the layers of the trunk-muscles can be explained in the living animal on physical principles.

2. With the small diathermancy of the muscular substance coincides its greatest power for absorbing heat, which at the ordinary temperature of warm-blooded animals may be placed at four calories.

3. The muscular substance possesses the highest known specific heat of solid and fluid bodies, and exceeds that of water considerably.

Further details are promised.

WM. STIRLING, D.Sc., M.B. (Edinburgh.)

WILDER ON THE ANTERO-POSTERIOR SYMMETRY OF LIMBS.—Professor Burt Wilder (*Proceedings of the American Association for Advancement of Science*, Aug., 1873, published 1874) hopes, by

means of embryology and the study of *Amphioxus*, to prove the existence of a true 'meketopy,' i.e. antero-posterior symmetry, in the vertebrata. He holds that there can be no escape from the conclusion that the anterior digit, or thumb, is the true homologue of the posterior digit, or little toe, and that the little finger is, in like manner, homologous with the great toe. All eminent Americans, e.g. Dana, Wilder, and the late professors Wyman and Agassiz, as opposed to English and continental anatomists, are agreed upon this point.

WILDER ON THE PECTORAL MUSCLES OF MAMMALIA, AND ON THEIR VARIATIONS IN DOMESTIC DOGS.—Professor Burt Wilder (*Ibid.* p. 305), believing that 'there is need of more accuracy in the dissection, delineation, and description of muscles, since at present there is great confusion respecting the nature of true muscular integers, and the basis of muscular homologies,' has been examining the pectoral muscles of mammalia. He prefers the terms *ecto-* and *ento-* pectoralis to those of pectoralis major and minor. The entopectoral is usually much the larger—thus belying the name generally given to it—the exception being found in man, the higher quadrumana, the bat, the bear, and the skunk. Its coracoid insertion is perfectly distinct in the Canidae and Felidae. The ectopectoral tends to separate into superimposed laminae, and, having an outward direction, it acts as an *adductor humeri*, while the entopectoral acts chiefly as a retractor of the shoulder, its fibres taking a direction obliquely from within, forward, and outward. It tends, moreover, to form fasciculi, corresponding in number to the costo-sternal articulations involved in its origin. In addition to the main pectoral mass, there are usually found one or more muscular elements, having variable relations. These are probably differentiated portions of the main pectoral mass.

In dissecting the pectoral muscles in nine different breeds of domestic dogs, Professor Wilder found a great uniformity in these organs; 'certainly no such differences as might be inferred from the external appearance of the breeds.' J. C. GALTON.

PATHOLOGY.

ROBIN ON EXPERIMENTAL SEPTICÆMIA.—Some contradictory results having appeared in this field of investigation, M. Robin has anew made fundamental experiments with reference both to the infectious power of putrefied blood compared with that of septic blood, and the septic activity of infinitesimal quantities of these two kinds of blood (*Comptes Rendus*, November 30). He used rabbits, as before; and he points out, as an indispensable condition, that the animals must be placed in free air, and be allowed liberty in all their habits. Wherever he has experimented, he has remarked that the slightest traumatism, in rabbits that are confined, infallibly give rise to disorders that prove fatal (more or less rapidly)—ganglionic congestion, tubercles, enteritis, etc.

A. Putrefied Blood.—Four series of experiments, each on a dozen rabbits, with the blood of a rabbit in full putrefaction, yielded the following results. 1. Injection, under the skin, of a dose of three, or two, or one, divisions of the small Pravaz syringe, caused the death of seven animals in a time varying

from three to six days, with the ordinary symptoms of infection. 2. Inoculation of the same blood with the lancet, killed only one out of nine rabbits, operated on at the same time with the nine preceding. 3. Inoculation of a few small grains of putrefied blood, previously dried, did not produce any result in nine rabbits thus treated. 4. Injection, under the skin, of three, four, and five divisions of the Pravaz syringe, of a liquid obtained by a dialysis of putrefied blood, gave no result in the nine rabbits thus treated. The blood had been left twelve hours in the dialyser, and the exosmotic liquid evidently contained bacteria similar to those of the blood, and traces of albuminoid matters.

A cubic centimetre of putrefied blood (killing rabbits in a quantity filling one to two divisions of the Pravaz syringe), if diluted immediately with distilled water to $\frac{1}{1,000,000}$ or to $\frac{1}{1,000,000,000}$ did not produce any disorder in four rabbits into which M. Robin injected $\frac{10}{27}$ of a cubic centimetre of this dilution. He was not more successful with progressive dilutions from $\frac{1}{20}$ to $\frac{1}{1,280,000,000}$. Seven rabbits were injected with $\frac{10}{27}$ of a cubic centimetre with dilutions of $\frac{1}{20}$, $\frac{1}{400}$, $\frac{1}{8,000}$, $\frac{1}{100,000}$, $\frac{1}{3,200,000}$, $\frac{1}{64,000,000}$, $\frac{1}{1,280,000,000}$. Of the seven, only one succumbed after three weeks, but without presenting septic alterations in the blood. The conclusion from these forty-seven experiments is, that putrefied blood, to be toxic, must be introduced into a rabbit's system in a proportion equivalent at least to one division of the Pravaz syringe; inoculations with the lancet, of infinitesimal dilutions, dialytic dilutions, do not produce fatal disorders.

B. *Infectious or Septic Blood*.—Having got, by successive inoculations, a blood decidedly septic, the author made similar experiments. Nine rabbits, into which he injected three, two, and one divisions of the Pravaz syringe of septic blood, all died in a time varying between sixteen and sixty-seven hours, presenting all the symptoms of septicaemia. Of seven rabbits inoculated with the lancet or the cataract-needle, seven succumbed like the preceding in less than four days; the two which survived did not show the least febrile disorder, and the author was led to suppose that there had not been real inoculation. Inoculation behind the ear of some powder of dried putrid blood, was fatal to six out of seven rabbits thus treated.

Putrid blood, dialysed during twelve hours, yielding a liquor slightly albuminoid, and containing microzymes, etc., in large numbers, was used to inoculate a series of nine rabbits, in a dose of 1, 2, 3, 4, 5, 6, 7, 8, 9 divisions of the Pravaz syringe. Of these nine animals, the last three succumbed with flagrant symptoms of infection; the sixth, fifth, and third had only slight fever; the first two showed no functional disorder.

Of six rabbits, into which were injected $\frac{10}{27}$ of a cubic centimetre of the following septic dilutions: $\frac{1}{8,000}$, $\frac{1}{160,000}$, $\frac{1}{3,200,000}$, $\frac{1}{64,000,000}$, $\frac{1}{1,280,000,000}$, $\frac{1}{25,600,000,000}$; only the first succumbed, after twelve days, with some septic symptoms; the others did not show the least functional disorder.

‘It thus appears that septic blood acts much more energetically than putrefied blood; that the “septicity” increases with the successive generations; that it remains the same, however small the quantity of inoculated blood, provided the inoculation is made without any mixture; and it is exceedingly probable

that the failures with infinitesimal or dialytic dilutions occur because the septic substance is not well mixed, and is not dissolved in the distilled water.’

FELTZ ON SOME EXPERIMENTS IN BLOOD-POISONING.—Feltz has found, as the result of forty-seven experiments, that putrefied blood introduced into the animal system must, in order to be toxic, be in quantity at least equal to one division of Pravaz's syringe. Inoculations by lancet, infinitesimal dilutions, dialytic dilution, do not give rise to mortal accidents. With quite fresh infectious or septic blood, it was found that blood thus contaminated is much more energetic in its action than putrefied blood; and that this is true, however small the quantity of blood inoculated. MEDICINE.

DUCHENNE DE BOULOGNE ON PHOTOGRAPHIC REPRESENTATIONS OF THE MINUTE STRUCTURE OF THE HUMAN NERVOUS SYSTEM.—Under this title we have a communication made by Dr. Duchenne to the Society of Medicine in Paris, on the occasion of his presenting an album containing sixty photographic representations of brain-structure. The part of the nervous system to which the communication is particularly devoted is the medulla oblongata. The object Dr. Duchenne had in view in selecting this part of the nervous centres, was the hope that he might therein find the explanation of the symptoms observed in cases of glosso-labio-laryngeal paralysis.

It was not until the author had been enlightened by Dr. Lockhart Clarke on the nature of the appearances he obtained, that he was able fully to comprehend their importance, and by their means to render more complete the morphological particulars already given by Dr. Clarke.

The symptoms of this particular form of paralysis, of which Dr. Duchenne was desirous to find the physiological explanation, are described as follows.

1. Glosso-labio-laryngeal paralysis primarily affects the pronunciation of the lingual consonants, later on that of the labials, and progressively the entire power of articulation. 2. About the same time deglutition is affected and becomes more and more impaired. 3. The voice becomes nasal, and the lateral movements of the lower jaw become paralysed. 4. In a more advanced period of the disease, the expiratory power is weakened and utterance diminished. 5. In the last period, the action of the heart is sometimes so profoundly affected that it may suddenly cease.

To account for these symptoms, Dr. Duchenne considered that it was necessary that one and the same lesion should be found to attack the origin of

the following nerves; the hypoglossal, the motor nerve-fibres of the velum palati, those of the lips, the spinal accessory, and perhaps the pneumogastric. By means of his photographic representations of several transverse sections of the bulb, Dr. Duchenne has been enabled to demonstrate the connections existing between the nuclei of these different nerves, and thus to prove the following occurrences. 1. The morbid process generally at first attacks the nucleus of the hypoglossal nerve, occasioning difficulty in the pronunciation of the lingual consonants. 2. The lesion, extending in the neighbourhood of the hypoglossal, attacks the inferior cells of the nucleus of the seventh pair of nerves, rendering the pronunciation of labials a matter of difficulty. 3. The same morbid process spreads to the spinal accessory nucleus, and thus progressively weakens bronchial expiration and phonation. 4. The demonstration of the position of the originating nerve-cells of the motor branch of the fifth pair of nerves, low down in the bulb, accounts for the nasal sound of the voice, also for paralysis of the muscles of the velum palati; and in particular, for the paralysis of the pterygoid muscles. 5. The extension of the lesion from below upwards, and the inclusion of the nucleus of the vagus, will account for the disordered action of the heart, and finally for sudden death. 6. The result of this inclusion of the nucleus of the pneumogastric during the gradual ascent and progress of the lesion will account for the fact that the muscles of the face, and other parts supplied by nerves from a point higher than the origin of this nerve, are not affected. It should, however, here be noted that Dr. Duchenne is not explicit on the nature of the lesion, or the mode in which he traces it from part to part in its alleged course. Starting from the results thus obtained, Dr. Duchenne alleges, regarding these photographic representations, that they show the structure of the anatomical elements as they appear on the field of the microscope, and therefore their exactness cannot be doubted; that they confirm and strengthen the observations of Dr. Lockhart Clarke; and lastly, that they assert superiority for the employment of photography, whereas other methods of microscopical drawing are necessarily only skeleton representations of the real appearances. W. KESTEVEN, JUN.

METTENHEIMER ON THE ETIOLOGY OF THE LOBULATED LIVER.—This paper was originally read on January 24 last, before a society at Schwerin, but now constitutes a large portion of Betz's *Memorabilien*, xix Jahrgang, 8 Heft. The preparation to which it refers was a typical specimen of lobulated liver, from a single lady aged thirty-eight. Mettenheimer remarks that most diseases of the liver can be more thoroughly studied in private practice than in hospital wards, on account of their chronic course. When first seen, the patient only complained of frequent severe headaches, compelling her to lie down, with which she vomited bile. These attacks seemed hereditary; all her living sisters are subject to severe hemicranial headaches. Her father died young of apoplexy. The mother died of 'consumption' at sixty-one years of age. The patient was delicate from childhood, but had never kept her bed. Her catamenia were always scanty and somewhat irregular, but never ceased till just before death. From her twentieth to her thirtieth year she was a governess. When about twenty-six she was chlorotic, and suffered from small ulcers in the left leg, the scars of which were yet visible. These lasted some time, but she entirely recovered, and never kept her bed

on their account. On being consulted the first time, vomiting induced Mettenheimer to examine the abdomen. The liver then extended about four finger-breadths below the margin of the ribs. It felt very hard, but smooth, not nodulated, not at all tender, and its upper border was normal. She drank very strong coffee, and indulged in sauces and highly seasoned meats. She was thin, but had a good fresh colour. The bowels were mostly constipated, but this seemed not to trouble her. She was rather excitable, and was able to indulge freely her gastronomic tastes, whilst exposed to frequent causes of vexation. These things probably had a share in causing her complaint. Passing over the remedies used for her sick headaches, vomiting, etc., it is to be noted that the hitherto smooth surface of the liver became somewhat suddenly elevated into nodules of a bullet-like form, and about the size of a pigeon's egg; there was a febrile movement about the same time. These nodules were easily felt in the epigastric region, and were very painful. Local blood-lettings acted famously, as stated by Hensch (Klinik der Unterleibskrankheiten, Berlin, 1863, 3 Aufl. s. 350), for the nodules became smaller and less tender. She afterwards benefited still further by a 'cure' at Carlsbad—so that the nodules were scarcely to be felt, except at the edge of the liver. Suspicions of carcinoma were entertained. Her emaciation favoured this. Mettenheimer had previously noticed the development of cancerous tumours in inflammatory attacks, and found them relieved by local blood-lettings [see his *Nosol. und Anatom. Beiträge zu den Greisenkrankheiten*, s. 95, 96.] The success of the Carlsbad 'cure,' more striking than in Oppolzer's case (Hensch, *loc. cit.* p. 148), raised a doubt as to malignancy. She gained flesh and felt pretty well. But the liver remained much enlarged, her bowels were constipated, and she had bilious vomiting. This was four years before her death. In the early spring of every year, her symptoms became aggravated; the feet and legs became œdematous—she had dyspnoea, etc. Local blood-lettings again relieved, but in the third year she once more went to Carlsbad—was relieved—but the state of the liver was still the same. In February, 1873, she became more emaciated, the catamenia were suppressed, the urine scanty, though it never became albuminous, even up to death. Ascites set in, and tenderness and pain over the liver grew almost unbearable. Morphia gave her more relief than any other treatment, especially checking rigors and coldness of the extremities, from which she suffered if she did not take morphia. The conjunctivæ were very slightly tinted, but her face acquired that brownish-green coloration, deeper as she grew thinner, which is so characteristic of this disease. There were copious perspirations every night. Acupuncture gave little relief, therefore paracentesis abdominis was performed; the enormous quantity of two and a half eimer (nearly twenty gallons) of clear yellow serum being evacuated. A second tapping, after three weeks, removed nearly eight gallons. Some improvement followed this, and the patient even began to walk about. Though resembling a living skeleton, she enjoyed life very fairly by the constant use of morphia. Death occurred eight months after ascites set in; she had then been tapped three times. Before death she suffered extreme pain, had aphthæ, lastly a rise of temperature, then coma, and in this she died. The *post mortem* examination

showed numerous adhesions between the abdominal viscera; the liver, pancreas, stomach, duodenum, and diaphragm were all closely adherent to each other. Numerous coagula and strings of fibrin were found, with turbid serum and other signs of chronic peritonitis. The liver was of very considerable size, occupying chiefly the right hypochondrium. It was an unshapely mass, composed of knobs of the size of apples (*sic*), separated from each other by strong connective tissue, which also interlaced them. The left lobe of the liver was a mass of the size of a fist, connected with the rest of that organ only by a short stalk. The enlarged spleen and some coils of intestine filled the left hypochondrium. The parenchyma of the liver was extraordinarily firm, cut with difficulty, was of dark-brown colour, somewhat marbled, rich in blood and pigment. The contracted gall-bladder was difficult to find, and contained numerous coffee-coloured calculi, of the size of a pin's head, or even smaller, and quite soft. The spleen was indurated, of the size of two fists. The kidneys were congested only. The uterus and ovaries were normal. The mesenteric and other abdominal glands were pigmented. Both pleural cavities contained serum. There was no tubercular disease of the lungs, nor cavities in these organs. The heart was diminished in all directions (microcardia). The right ventricle of the heart was as thin as paper. There was concentric hypertrophy of the left ventricle; it would hold scarcely a thimble-full of blood. There was slight atheroma of the bases of both aortic and pulmonary valves. There was no other valvular disease.

In commenting on the case, Mettenheimer considers it to have begun in a localised hepatitis—which afterwards led to the formation of nodules—or lobulation. [Fig. 4, p. 75, and fig. 5, p. 85, of vol. ii. of Dr. Murchison's translation of Frerichs on the Liver, New Sydenham Society, give a good idea of the 'lobulation' or nodulation just described.] He remarks that anatomists, such as Rokitsansky, draw a sharper line of demarcation between this and the common form of cirrhosis than do clinical observers such as Frerichs, whose eighteenth case the one above resembles [*loc. cit.*, p. 85]. The commonest cause of this condition is syphilis, as alcohol is of the cirrhotic liver. The two authorities quoted, and Budd also, agree in this. As regards our case, there were no proofs of this. She had intact and virginal genitals. The only symptoms in her history the least suspicious were the ulcers on the legs. They were, however, regarded as varicose, and healed easily by simple remedies. The false membranes at the apices of the lungs are found in other diseases besides syphilis. May the syphilis have been congenital? There is no evidence, save the negative statements of her sisters. Both parents are long since dead. The strong coffee, pickles, spiced comestibles, and frequent mental perturbations of our patient, were doubtless the cause of her attacks. He does not think the nodules were ever abscesses, only hyperplastic formations. Probably Oppolzer's case of cancer, ameliorated at Carlsbad, resembled this, though Virchow (*Krankhafte Geschwülste*, vol. ii. p. 428) seems to think it a gummatous formation. There was no waxy degeneration in the spleen or liver, or of any other organs of our case. Ascites is not easy to recognise in an early stage; it therefore seems unwise to lay much stress on the priority of this or of oedema of the feet, as a diagnostic sign of liver disease, or of cardiac and pulmonary mischief.

The microcardia was probably partly congenital, partly a symptom common to other muscles, which were much wasted all over the body. Concentric hypertrophy of the left ventricle is not uncommon in cases of small heart. (See Bouillaud; and Mettenheimer's *Beobachtungen über die typhoiden Erkrankungen der französischen Kriegsgefangenen in Schwerin*, Berlin, 1872, s. 49). It is notable, that till just before death, there was never any suppression of bile, nor any abnormal quantity of bile-pigment in the urine. W. BATHURST WOODMAN, M.D.

SURGERY.

SÉDILLOT ON TREPHINE-WOUNDS AND THEIR DRESSING.—Means of medical treatment rest generally on exact observation, which, however, is often isolated and partial, and thus the same problems recur at different times to be studied under better lights. The influence of air upon the human patient, sick or wounded, has been a subject of constant research, it may be said, since the time of Hippocrates; and now infectious, contagious, putrid, gangrenous, and pestilential affections, are attributed to miasms or other toxic and parasitic elements contained in the atmosphere, and determining local or epidemic accidents of very variable extent and gravity. Surgery has recognised from all time the action of the air upon wounds, and the *Académie de Chirurgie* at the end of the last century chose for its prize-subject the question—'On the Influence of the Air in the Treatment of Wounds.' The application of balsams, unguents, aromatics, camphor, certain metallic preparations, alcoholates, camphorated *eau-de-vie*, found its partisan in each case. These questions, however, have not ceased to be discussed, and we commence at last to comprehend the high importance of media, the knowledge of which is indispensable to a rigorous appreciation of biologic phenomena.

Such was the state of surgery relative to the dressing of wounds, when the experiments of Pasteur led to the supposition that ferments were the sole cause of infectious complications, and that it would be possible to remedy these by sheltering the wound from the atmospheric protozoic elements. The question was of too great interest not to be at once studied.

The most able experimentalists (and it is sufficient to cite the name of M. Dumas) have compared the action of numerous substances which prevent or arrest fermentation. Carbolic acid, recommended by Dr. Déclat, who, more than anyone, has generalised its use, and by Mr. Lister of Edin-

burgh, whose carbolic dressings are universally known, was declared a most powerful antiseptic. Phenol, coal-tar, tar, alcohol, alcoholates, hyposulphite of soda, various slightly caustic solutions, etc., have been tried and recommended.

Filtration of the air by carded cotton, proposed by Pasteur as a means of purification from panspermic germs, has become a prophylactic method against traumatic infection; and now that these modes of treatment are multiplying, we may discuss and compare their advantages.

The success of trephining seems due to antiseptic dressings, to washing (in Sédillot's special cases) the wound with an aqueous solution of hyposulphite of soda and of carbolised alcohol (one in ten), and applying a plaster composed of thirty parts of glycerine and one of carbolic acid, with pulverised chalk mixed to a semi-liquid paste, spread upon tinfoil and covered by a bandage.

The problem of this treatment of wounds presents four factors, whose combinations are very complex:—

1. The known or supposed ferments:
2. The media in which these ferments are developed:
3. The state of the organism and of the traumatism:
4. The antiseptics intended to prevent and combat local and general effects of ferments.

1. There have been classed, according to Cagnard de Latour and Turpin, a large number of ferments; but there are still among the unknown those supposed to be the cause of infectious and contagious maladies, such as erysipelas, hospital fever, carbuncle, etc. The origin, organisation, modes of propagation, and multiplication of the different species, their varieties of action or of nocuity, are equally open questions. Septicæmic blood, prepared by M. Davaine, killed some of the animals experimented with even in infinitesimal doses; and if atmospheric ferments are so redoubtably the source of traumatic complications, it is none the less true that the most dangerous wounds are habitually without accident when the surrounding air is not vitiated. May we not then conclude that there is little danger of panspermic changes in the normal conditions of life? This danger arises with the courses favourable to the multiplication of fermentary corpuscles.

2. The consideration of favourable or specific media occupies an important place in the problems to be solved. Heat and humidity, decomposition of animal and vegetable matters, large collections of living beings (towns, hospitals, camps, etc.), confined air, all play an important part in the production and propagation of epidemics.

3. Men offer to these ferments resistance that varies greatly, with race, sex, rank, idiosyncrasy, age, constitution, state of health, etc. Certain individuals are particularly accessible to morbid causes. The least scratch will determine with one an abscess, with another gangrene and the most deplorable accidents, whilst with others the deepest and largest wounds are very readily healed. Wounds, according to their nature, their causes, and their irregularities, are not exposed to the same chances of infection. Thus the conditions to be analysed in order to draw certain conclusions and determine error are very complicated.

4. The means of preventing and combating the effects of ferments on wounds form another kind of study. Filtration of the air, the immense pan-

spermic recipient, appears the prophylactic process that is most effectual; whilst the curative treatment comprehends the destruction of ferments by antiseptic substances of external or internal application. If the ferments have already penetrated the organism and render it necessary that we should pursue them there, how are we to destroy them without alteration to the elements with which they are bound up? We may cite, as examples, the success of vaccine against variola, of quinine against certain fevers, of mercury against syphilis; but nothing goes to prove that these maladies are due to ferments, and their generalisation as parasitary ferments, although in itself rational, still requires scientific demonstration.

A dressing for trephine-wounds that has been successfully used by Dr. Sarazin, surgeon-major to the Military Hospital at Bourges, is a solution of ten per cent. of tar in water made alkaline with soda without causticity. This liquid cleanses and rapidly disinfects the wound, which may be covered with a layer of tar and wadding, in two courses, to a finger's thickness. This dressing has been used in a case of amputation of the thigh, two of the leg, three of the breast, a resection of the elbow, one of the knee, and in many cases of wounds by fire-arms, etc. The many cases of resection of the knee successfully accomplished by antiseptic aid, indeed, may be considered scientific evidence of the value of this comparatively recently introduced system of medicine.

MATERIA MEDICA AND THERAPEUTICS.

GRIFFITHS ON CHEMISTRY IN ITS RELATIONS TO THERAPEUTICS.—In the *Medical Press and Circular*, Dr. W. Handsel Griffiths discusses the relations of recent chemical researches to therapeutics. The researches, which give promise of the most useful results, are:—1. The chemistry of the tissues and secretions; 2. The connection between the chemical constitution of the agent and its physiological action; 3. The chemical changes undergone by drugs after absorption. In 1841, Blake stated that the salts of isomorphous bases have a more or less similar action. In 1868, Dr. W. H. Broadbent maintained that 'substances chemically allied should have similar physiological and therapeutic actions, or any diversity found to exist should be capable of explanation on chemical grounds.' Drs. Crum Brown and Thomas Fraser showed that the physiological action depends upon the chemical constitution as well as composition of a drug. Acetic acid and sugar, and glycocoll and nitrite of ethyl are identical in composition, yet differ in physiological action. They also showed that the action of a substance may be altered by introducing into it a definite chemical change without breaking up its molecule. By adding iodide of methyl to the non-saturated base strychnia, its poisonous properties were greatly diminished. Jolyet and Cahours conducted about the same time similar investigations. By substitut-

ing an organic radical for an equivalent of hydrogen in certain compounds, they endeavoured to determine whether such substitution would modify the physiological action of the compound. They found that, while aniline produced convulsions by exciting the cerebro-spinal centres, ethyl-aniline, methyl-aniline, and amyl-aniline abolished the function of those centres. Rabuteau has recently enunciated the law that metals are more active physiologically, according as their atomic weights are higher or their specific heats are lower. The monatomic metalloids are governed by a law which is the reverse of this. The metals rubidium, tungsten, and molybdenum are exceptions to the law. Dr. B. Ward Richardson has drawn attention to the fact that the number of atoms of carbon contained in an alcohol appears to serve as an index to its activity, as may be seen by comparing the respective activities of ethyl and amyl alcohol. M. Gubler maintains that, 1. Substances when absorbed tend towards their similars or analogues; 2. When a substance cannot meet with its similar or analogue, it must be eliminated; 3. It is eliminated by the channel in which it meets with similar bodies. [M. Coze, of Strasburg, upwards of thirty years ago, enunciated almost exactly similar laws.—See *American Journal of Medical Sciences*, April, 1843, p. 438.—*Rep.*] M. Onimus has found that the interposition of a layer of some albuminous substance, as the white of an egg, between two liquids, often gives rise to electrochemical phenomena, a discovery which may lead to valuable results to therapeutics. The discovery of the action of chloral, by Liebreich, has given an impetus to the study of the decomposition of chemical agents in the organism. M. Byasson thinks that the longer duration of the action of chloral than that of chloroform, is due to the slowness of the chemical action, and that the difference of their action is explained by the intervention of formic acid, produced in the case of the former drug. M. Personne, on the other hand, believes that the combination of the chloral with the albumen will explain the differences in their action.

JAMES ROSS, M.D.

RABUTEAU ON A NEW REMEDY: THE YERBA DEL PERRO.—At the meeting of the Biological Society of Paris on December 5, M. Rabuteau presented a new Mexican plant of a poisonous character, the *Yerba del Perro*, which had been sent to him by M. Victor Salet. He had tried its therapeutic properties on dogs, and found that they raced about, were much disturbed, had convulsions, and died in the short space of ten minutes.

The extract is very deliquescent. Eighty centigrammes (twelve grains) injected into the veins of a medium-sized dog produced the following effects. There was nothing remarkable until an hour had passed; at the end of that time, the dog barked a great deal, foamed very much at the mouth, and fell down in convulsions. These symptoms lasted during half an hour, when the animal died. This new plant produces symptoms analogous to strychnine, but the convulsions produced are of a different character. In the dog which was first experimented on, the pupils were enormously dilated; the brain was congested, but not the spinal marrow; the lungs were in a normal state. This *Yerba del Perro* (dog-grass) belongs to the family of Compositæ; it has a woolly stem, and seems to be highly poisonous.

OBSTETRICS AND GYNÆCOLOGY.

EMMET ON REMOVAL OF UTERINE FIBROID.—Dr. Emmet reports (*American Journal of Obstetrics*, August, 1874) a case of fibroid tumour of the uterus removed by him the day before. The patient had been suffering from excessive metrorrhagia during the past month, which had been controlled only by the constant use of styptic injections. The uterus was anteverted, and its cavity occupied by a fibrous tumour of the size of a fist; the sound could be introduced to the depth of five inches posteriorly and of three inches anteriorly. Suppositories of gelatine, containing each 16 grains of Squibb's aqueous extract of ergot (equivalent to about 100 grains of powdered ergot) were introduced into the rectum, where they produced but little effect, and then daily, during the last ten days, into the cavity of the uterus itself, with marked beneficial results. The uterus, which at first had been more elongated and pear-shaped, now became broad at its fundus, where it measured no less than four inches; the tumour thus approached the internal os, although its broad attachment to the uterine wall was in no way changed. The great difficulty was to get an instrument or a loop behind or around the tumour, in order to effect its removal. Dr. Emmet retroverted the uterus, seized the fibroid with a double tenaculum, and proceeded to draw it down towards the vulva, in which attempt he succeeded after about half an hour's steady traction, removing portions of the tumour with the scissors as it became attainable. When the fibroid had been brought down to the vulva, Dr. Emmet thought he was inverting the uterus, at which prospect he was not alarmed, for he knew that he could easily return it at once; he found, however, that the uterus had contracted behind the tumour as it was drawn down, and had thus by its individual efforts enucleated the base of the tumour, and at the same time prevented hæmorrhage, and made it necessary only to divide the capsule of the fibroid with the scissors in order to remove the whole growth. During the whole operation, which lasted about an hour and a half, hardly a drachm of blood was lost, and that came from the laceration of the fibroid by the double tenaculum. The base of the tumour measured about two inches in diameter; after its removal, only a slight depression could be felt at the fundus to indicate the spot where it had been attached. After the operation he followed his usual rule of washing out the uterus with warm water, and painting the whole of its cavity with Churchill's tincture of iodine, as a precaution against septicæmia.

This is the most difficult case of the kind he has seen. A few years ago he removed a similar tumour

in the same manner, but did not fully understand the *rationale* of the operation until lately. The steady traction used arrests hæmorrhage, because it excites the uterus to contract behind the tumour as it is drawn down, and thus to compress the bleeding vessels, besides bringing the fibroid nearer and more convenient for removal. It is not the forcible traction of the fibroid towards the os, that is, in the direction of the least resistance, but the *vis a tergo*, the contraction of the uterus behind the tumour, which gradually lifts the latter from its bed and enucleates it. This steady traction may be of service, if repeated at regular intervals, in bringing uterine fibroids within reach and making them amenable to operation, and may, perhaps, even accomplish their gradual enucleation.

SCHULTZE ON A CASE OF DOUBLE MASTODYNIA WITH SECRETION OF COLOSTRUM.—Dr. F. Schultze relates in the *Berliner Klinische Wochenschrift* for October 19, 1874, a case in the clinic of Professor Friedreich of Heidelberg.

It occurred in a married woman, aged twenty-six, the mother of one child, which she had suckled only for six weeks; her milk, which was plentiful before, disappeared suddenly through mental distress, without any pain. Menstruation returned, and continued to be normal up to her admission into the hospital in June, 1873. She stated that about seven months before her admission, and about four months after an acute attack of rheumatism, she was suddenly seized with sensation of fullness of the right breast, as if 'the draught' had come in; this continued, and on squeezing the gland, milk squirted out. The feeling of distension subsided the next day, and most acute pains in the breast came on. Five days afterwards the left mamma was similarly affected, and pain attacked both, mostly the left. At first there were intervals of entire freedom from pain, but during the last few weeks before entering the hospital the suffering was continuous, only exacerbations and remissions being observable. She was anæmic, but well nourished; the breasts were moderately pendent; palpation discovered nothing abnormal, and nowhere were there any painful nodules, nor were the glands anywhere sensitive. A few drops of a yellowish fluid could be squeezed out of the breasts, which exhibited microscopically all the characters of colostrum. There was tenderness over the dorsal vertebræ from the second to the tenth. All the thoracic and abdominal organs were normal. There were no signs of extra-uterine or uterine pregnancy, only some leucorrhœa and slight redness at the vaginal orifice.

The patient was kept nine months in the hospital, and every conceivable method of treatment was adopted; medicines of all sorts, subcutaneous injections, electricity, galvanism, and the continuous currents. The sufferings of the patient fluctuated under these various methods of treatment; at times showing improvement, at others the reverse.

The pain in the right breast was generally in its upper half, over the collar-bone and through the shoulder; in the left, in its lower half, and down the same side. The left mamma was, as a rule, the more painful during her stay in the institution. On stooping she frequently felt a sensation as if the breasts 'would fall out.' Repeatedly, every fourteen days, for about two or three times, she experienced a peculiar feeling of chilliness in both mammae, which

lasted for some hours; there was also at times some formication, but never any anæsthesia of the skin.

Distinct symptoms of hysteria never showed themselves; menstruation was not very regular either as to quantity or to time; latterly, during the periods, the pain in the breasts increased, the mammae becoming tense and full; the secretion at these times was clearer, more like serum, with fewer milk-globules and less appearance of milk.

Pure uncomplicated mastodynia is stated by Broca never to exist, whilst some of the older German writers mention it as a 'tolerably frequent affection, especially in delicate nervous women.' Eulenberg believes it to be one of the rarest and most obstinate forms of neuralgia; be that as it may, it is certain that to find it accompanied with a secretion of milk is a rare and remarkable occurrence.

Galactorrhœa, whether in old or unimpregnated women, or in men, is by no means an exceptional event; but there is no instance in literature of a pure mastodynia coupled with a secretion of milk. Beigel's well-known case differs in this respect from the above, that the milk came first, the pain afterwards; whereas in Professor Friedreich's case the pain was first, the milk-secretion followed. He believes he is not wrong in attempting to explain his case by analogy with neuralgia of the trifacial, where there is an immense secretion of the lacrymal gland, through irritation of the lacrymal nerve. So also in neuralgia of the nerves supplying the skin (*Hautnerven*) of the gland, the nerves of secretion may become irritated, causing a flow of milk, or it might be that the nerves of secretion and sensation were affected by one and the same irritation, which would produce the self-same effect. It is remarkable, considering the intimate relationship between the nerves of the skin and the nerves of the gland, that this affection is not more frequent. It could hardly have escaped the notice of careful observers if such were the case.

BIDDER ON A CASE OF SUBMUCOUS FIBROID OF THE UTERUS.—Dr. A. Bidder of Mannheim (*Berliner Klinische Wochenschrift*, Nov. 16, 1874), reports a case of large submucous fibromyoma, growing with a broad base from the anterior wall of the uterine cavity. He pulled it down to the vaginal orifice and cut it away with the scissors, applying the actual cautery to the raw surface to prevent hæmorrhage, which was slight during the operation; rapid cure followed. The following are the more important features in this case. The uterus was anteverted and above the pubes, freely movable, with a subperitoneal fibroid at the fundus; the os was nodular and admitted the tip of the finger; examined during menstruation, the os was dilated about five centimètres, encircling a smooth, round solid mass projecting into the vagina; the finger could not reach up quite as far as the upper border of its seat of attachment, even when the uterus was powerfully depressed through the abdominal walls. When re-examined after the hæmorrhage had ceased, the cervix could now only admit two fingers, and could reach no higher although it was pulled down with Museux's hooked forceps. Bleeding returning, an injection of a solution of iodine of the strength recommended by Savage, was injected into the uterine cavity which had the effect of arresting the hæmorrhage, and causing the tumour to descend still lower through the os, with, it is true, intense pain. The tumour was close upon the outlet. The top of the insertion of the body

was now felt for the first time; the base was more than six centimètres wide. It could be drawn through the vaginal orifice easily with the hooked forceps; the insertion was about twelve centimètres long and nine centimètres wide; there was no proper pedicle. A thick thread was passed through at its border between the tumour and the uterus. The écraseur (Mayer and Meltzer's) broke. The scissors were used to divide the bands of loose connective tissue between the capsule and the tumour. Little blood was lost. As a precautionary measure, the whole surface of wound was cauterised by the actual cautery, then bathed with ice-water; the thread was removed, and the uterus replaced. An ice-bag was applied to the abdomen for three days; the temperature rose the first two days, then became normal and continued so. Menstruation returned the next month with moderate loss, and since then has been normal. The effect of the injection of the iodine solution is particularly noteworthy, as stopping the hæmorrhage and exciting contraction of the uterus, which considerably aided its removal. W. C. GRIGG, M.D.

SPIAGGIA ON A CASE OF THROMBOSIS OF THE UTERO-OVARIAN VEINS, WITH METASTATIC ABSCESSSES IN THE LUNGS.—Dr. Salvatore Spaggiaglia describes this case in the *Gazzetta Clinica della Spedale Civico di Palermo*, fasc. ii. & iii., 1874. The patient was a woman, aged thirty-nine, who had been married twenty-two years, and had had five children and two abortions. In December, 1873, she was attacked with slight rigors, followed by great rise of temperature. The attacks recurred daily, from the 17th to the 31st, on which day she aborted. Quinine was given; the febrile paroxysms, however, continued. On January 31, she was admitted into hospital. There was found to be considerable enlargement of the spleen, with disturbance of the circulatory, and especially of the respiratory organs. She rapidly grew worse and died.

At the necropsy, thirty-two hours after death, the lungs were found to be almost universally adherent to the thoracic walls, and were literally stuffed with purulent deposits of various sizes. In a portion of the right pleura which remained free from adhesion, about 400 grammes (fourteen ounces) of sero-purulent fluid were found. The deposits contained pus-globules, fat-granules, and débris of pulmonary tissue, immersed in a fluid, which to the naked eye had the appearance of milk rather than pus. The bronchial mucous membrane was uniformly reddened; the pulmonary tissue surrounding the deposits was reddened and hard (as if hepatised), and presented signs of interstitial hæmorrhage. The arteries and veins in many parts of the lung were full of white or rose-coloured friable coagula, fibrin, fat-granules, and pigment. The pericardium contained a little yellow serum; the heart was flabby. The liver presented the characters of nutmeg-liver, and was closely adherent to the diaphragm. The lower vena cava, where it was in contact with the liver, had a third of its periphery lined with a layer of matter resembling coagulated fibrin, of a dirty white colour, dense, and finely granular; it was readily torn in attempting to remove it. This substance extended as far as the surface of the utero-ovarian vein, which was completely obliterated by a whitish hard coagulum. The spleen was doubled in size, and the kidneys were anæmic and softened.

Dr. Spaggiaglia believes that the morbid process

commenced in the utero-ovarian vein in consequence of the pressure of the uterus; that the thrombus extended into the cava, where it became softened; and that portions were carried into the circulation, and, being arrested in the small branches of the pulmonary artery, produced the abscesses in the lung. A. HENRY, M.D.

CURTIN ON ANTENATAL ERUPTION OF THE TEETH.—Dr. Curtin gives an account in the *Clinic* of November 21, of a case of this description. According to his account, the child, which was normally constituted otherwise, had nine perfect teeth when born. He goes on to say that the child was first visited by him when it was four weeks old (January 27, 1874), in company with Dr. James S. Myers, who had seen it previously, and very soon after its birth. They found an emaciated male infant, evidently suffering from marasmus and near its death, having five teeth in place and four distinct conical fleshy papillæ, from which a corresponding number of teeth, two incisors and two molars, had already been removed. These teeth loosened of their own accord, and not from the pressure of others from beneath. In addition to these, a number of small whitish nodules could be seen and felt along the line of the gums, above and below, lying underneath the mucous membrane, and evidently marking the place of all the other deciduous teeth. No change took place in these up to the time of the child's death, which occurred at the sixth week.

PSYCHOLOGY.

GRAY ON THE PATHOLOGY OF INSANITY.—Dr. Gray, New York State Lunatic Asylum, Utica, in an able paper upon the pathology of insanity (*American Journal of Insanity*, July, 1874), introductory to a portfolio of photo-micrographs of morbid appearances observed in patients who had been under his care, states that these illustrations embrace healthy brain-tissue, acute, subacute, and chronic mania, melancholia, in acute and chronic stages, dementia, general paresis and epilepsy; and in connection with each is a descriptive text, presenting a brief history of each case. These investigations embrace the microscopic examination of fifty-two cases, and especially the changes found in the vessels, nerve-fibres, cells, and neuroglia or connective tissue. The history of the mental manifestations has been epitomised; the description of the morbid appearances, as represented in the plates, is given almost verbatim.

I. *Chronic Mania*.—*A. History*.—M., aged sixty-two, laboured under mania of suspicion for some years. Memory impaired; miserly in habits; hoarded; untruthful; feeble in intellect. Disease aggravated by law-suit; incoherent and excited in court. Lost sleep and appetite, and emaciated rapidly. Became maniacally violent, and resisted interference. Destructive, cutting hands, etc. Continued in this state, and died a week after admission to asylum.

B. Morbid Appearance.—In a section through the third left frontal convolution, the degeneration was in a most advanced stage. The masses were distinctly isolated from the surrounding tissue, which had partly undergone slightly fatty changes. The concentric layers of connective fibres which formed the cavity in which the masses were contained, appeared distinctly around the mass, whose gelatinous semi-fluid aspect contrasted strongly with the granular structure of the rest of the brain. The microscope showed the nerve-element very much marked by a fine dark granular matter, not dissolved by ether, becoming more distinct in its granular compositions when treated by acetic acid. The connective fibres and nuclei could be made out in the middle of the substance, but the more conspicuous character of the alterations was the presence of large ovoid or spherical products, changing in appearance from a finely granular pellucid mass to a semi-gelatinous or diffuent fluid. These morbid products were surrounded by condensed meshes of connective fibres forming a true cystic cavity, from which the contents might be easily removed. In their solid form these products were very friable. Indications were noticed that the necrobiosis had in certain places reached an advanced fluid stage preliminary to the re-absorption of the cystic contents observed at the later period of the degenerations, where the true lacunæ replaced the pre-existing morbid contents. A proliferation or hyperplasia of the fibres of the neuroglia was observed, but not the proliferation of nuclei, nor the distension of the lymphatic sheath which surrounded the vessel by the collection therein of fatty globules. It was inferred from the characters of fatty degeneration and non-proliferation of nuclei, etc., that these structural changes differed from those observed in sclerosis.

II. *Melancholia, Chronic*.—*A. History*.—F., aged fifty-seven, mother of eight children; hereditary tendency. Previous psychical condition not known. Temporary convalescence followed by loquacity, incoherence, destructiveness. Refused food; lost flesh and strength; became pale, anæmic, continued maniacal, but gradually failed and died in eight months from diarrhoea.

B. Morbid Appearances.—In a section through the medulla, the character of the degeneration was demonstrated in the different stages of development. Small or larger well-defined semi-transparent spots of a granular substance, reflecting the light with brilliancy, but not tinged by carmine, and not soluble in ether, alcohol, or chloroform, surrounded by a proliferation of connective fibres, indicated the earlier degrees of this alteration. In more advanced stages the mass reached a semi-fluid condition. It should be remarked that this change, which may resemble a state of sclerosis, differs in its character from the condition described, which in no instance, as we are aware, leads to the complete separation of the morbid product within a well-defined cavity, nor to the entire absorption of encysted morbid products.

III. *General Paresis*.—*A. History*.—M., aged twenty-nine; no hereditary tendency; accustomed to liquor and tobacco. In good health till attack of right hemiplegia four years ago. Diphtheria. Injurious effects of overdose of acetate of lead; convalescent for two years. Mental excitement; complained of fancied blow on head; extravagant delusions as to extensive purchase; unsteadiness of gait; simulated drunkenness; ordered carriage; etc. Became maniacal and was taken to prison. Extravagant delusions as to power; wealth; hesitancy of speech; vacillation in walking. Tremor of tongue and fingers, and loss of co-ordination of the latter. A parietic convulsion, followed by apparent restoration to health, with appreciation of condition and its issue. Repeated convulsions, and gradual failure and death after fourteen months.

B. Morbid Appearances.—Advanced fatty degeneration was observed in the anterior roots of the cervical nerves. There was rupture of the axis of the fibres, and accumulation of granules in the posterior columns and the long vessels. The medulla oblongata and pyramidal bodies were of small size and indurated. There was atrophy of the roots of the hypoglossal nerve. The fibrillar structure was indistinct. Pigmentary degeneration of the large ganglionic centres near the septum was noticed. There was slight pigmentary degeneration of the centres of the roots of the vagus and facial nerves. There was general atrophy of the nervous element of the third convolutions in both hemispheres. The pyramidal cells were diminished in number, but hypertrophied in the left parietal convolutions. The spindle-shaped cells of the inner layer were frequently in a state of granular degeneration. Deposits of fatty and crystalline masses existed in the grey substance, and irregular proteinous bodies between the fibres of the white substance of the convolutions. The vascular system exhibited extensive degeneration. The walls of the smaller vessels were frequently found thickened, swollen, and infiltrated by a homogenous hyaline substance. In other cases the larger capillaries showed themselves manifold, curved, distending the adventitious membrane between the curves, and giving rise to accumulations of lymphatic elements, fatty granules, and pigment-bodies; others were surrounded by a dense layer of nuclei, surpassing three or four times the inner space of the vessel; and others were involved by cell-bodies of a spongy-like structure. A section through a part of the pons Varolii, near the roots of the trigeminus, showed numerous deposits of proteinous bodies between its fibres and the surrounding tissue. A section through a part of the medulla near the raphé showed colloid bodies.

IV. *Epilepsy with Dementia*.—*A. History*.—M., aged nineteen. Epilepsy for nine years. Habits good. Mind feeble; taciturn, indifferent. Fits daily. Lost control of sphincters. Kept in bed. Refused food, except bread and milk, which he took freely. Died in a fit.

Morbid Appearances.—*B.* Fine fatty granular degeneration interspersed with amyloid corpuscles were seen in the medulla and olivary bodies, and in the third left anterior convolution as well as in other sections of the brain. A section through the spinal cord, opposite the first cervical vertebra, showed portions of the posterior columns in which the multipolar cells were seen filled with pigment. The granular amorphous matter was considerably increased, and mixed with very fine transparent fibrils of connective tissue and very small connective nuclei. A section through the middle cervical ganglion of the sympathetic

showed the same fuscous or pigment-degeneration of the ganglion-cells, with a very marked hypertrophied condition of the connective tissue.

V. Subacute Mania (Syphilis). A. M., aged twenty-five. Patient intemperate. A clerk and canal officer; dissolute; contracted syphilis; health failed, but still addicted to drinking and dissipation. Threatened life of father. Secluded himself; went through house semi-nude; feverish, delirious; still drank largely; was abusive, violent, riotous. Wounded an inmate with a pistol, and subsequently shot his stepmother, whom he asserted he was commanded by God to kill for attempting to poison him. On admission, thin, pale; tongue coated; features sharp. Sinuses in hand and foot. Restless, loquacious, discontented. Ate and slept well, but denied doing either. Tumor of left leg and foot, with bullæ; sinuses in nates; impairment of strength; hæmorrhage; died in six hours. No aphasia; limited delusions. Coherent and conscious of condition. **B. Morbid Appearances.**—The nerve-centres, as well as all the viscera of the body, had undergone the fatty degeneration observable in constitutional syphilis. The contrast between degeneration in these two cases was very marked. A section of the left frontal convolution at the union of the grey and white substances showed the dark outline of the globules as having a very brilliant and transparent appearance. Section of medulla across the olivary bodies, and of the posterior nerve-roots of the cord, showed one of the large masses split up, and others developed in the midst of thick meshes of fibres, and encroaching upon the adjacent nerve-fibres.

VI. Acute Mania.—A. History.—F., aged thirty-six; healthy, but exposed to great anxiety by domestic affliction. Depression; suspicious as to fancied conspiracies; irritable, profane, obscene, and then maniacal; pale; anæmic; rapid and feeble pulse; surface cold; headache; noisy, incoherent, restless, vigilant; appetite variable. Death preceded by increased restlessness and resistance. **B. Morbid Appearances.**—Capillaries characteristic of acute mania. The earliest accumulations of granular masses were around the nuclei of the adventitious membrane. In a further advanced stage, a part of the vessel was surrounded with granule-cells. Thirdly, there was entire involvement of the vessel by the fatty granules; the accumulation exhibiting a crystalline and atheromatous condition. The larger cells of the middle layer of the cortical substance, especially of the hemispheres and the Sylvian fissures, were puffed out and remarkably enlarged, their contents forming large globules, distributed in half circles around the enlarged transparent nuclei, the nucleoli of which were only very rarely pronounced. In certain sections from the Sylvian convolutions, the outlines of the cells could not be traced. W. A. F. BROWNE.

REVIEWS.

On Functional Derangements of the Liver. By CHARLES MURCHISON, M.D., LL.D., F.R.S., Physician to St. Thomas's Hospital, etc. London: Smith, Elder, & Co., 1874.

In his Croonian Lectures at the Royal College of Physicians, in March last, which were reported in the *British Medical Journal* (and in the *Lancet*), Dr. Murchison has fully vindicated the claims of the liver to a large share of attention from pathologists and practising physicians. These lectures have now been reprinted, with additions, in a very neat form; and some woodcuts of leucin, tyrosin, and other microscopic objects are inserted in the text. The functions which Dr. Murchison alleges the liver to possess are the following.

1. It is one of the organs mainly concerned in the process of sanguification; not only as forming glycogen and fat, but as increasing the number of leucocytes (Bernard, Lehmann, McDonnell, Hirt, Weber, Kölliker, etc.), and probably of red corpuscles also.
2. It is not only a blood-forming, but a blood-destroying or purifying organ, and contributes in a great degree to the destruction of albuminous matter derived from the food and textures, and to the formation of urea and lithic acid, subsequently eliminated by the kidneys (Lehmann, Brown-Séquard, Gréhaut, Legg, Bence Jones, Parkes, Cyon, etc.).
3. The next function of the liver is the secretion of bile. Dr. Murchison combats the idea that bile-pigment is formed in the blood, and believes that this, as well as the biliary acids, are formed by the liver. He thinks (with Dr. Carpenter) that about forty ounces of bile are a fair average daily quantity for a man of eleven stone weight.

These three functions, taken together, show that 'the liver contributes to the maintenance of animal heat, to the nutrition of the blood and tissues, to the development of white blood-corpuscles, to the purification of the blood, the elimination of much nitrogen and carbon, the assimilation of fat and peptones; whilst some of the bile, in passing along the bowels, stimulates peristalsis and arrests decomposition.'

The functional derangements of the liver are classified by Dr. Murchison as follows:—1. Abnormal nutrition; 2. Abnormal elimination; 3. Abnormal disintegration; 4. Derangements of the organs of digestion; 5. Derangements of the nervous system; 6. Derangements of the organs of circulation; 7. Derangements of the organs of respiration; 8. Derangements of the urinary organs; 9. Abnormal conditions of the skin. [The reporter thinks abnormal conditions of the generative organs might well be added to this list, particularly in females.] Under these various heads, the following conditions or diseases are shown to be caused or aggravated by functional derangements of the liver. 1. Corpulence; 2. Emaciation. [This paradox is well known to practical men, and explanations are offered by Dr. Murchison.] 'Diabetes also may be said to be, in most instances, a functional derangement of the liver. The various causes of glycosuria may be said to come under one of the three following heads; a. Imperfect glycogenesis in the liver; sugar swal-

lowed and not assimilated, appearing in the urine ;
b. An increased conversion of glycogen into sugar ;
c. Diminished destruction of sugar.' 3. Phthisis and waxy disease, and other wasting diseases, are not improbably connected with some functional derangement of this organ ; 4. Deficient elimination of urea, leading to convulsions, coma, and death [not cholestæmæmia, but uræmia.] ; 5. Lithæmia, or excess of uric acid in the blood. This word is proposed by our author instead of Dr. Austin Flint's 'uricæmia'—it signifies what many people call 'masked gout,' and partially explains gouty dyspepsia, and gouty neuroses. Gout itself, urinary calculi ; 6. Biliary calculi ; 7. Many diseases of the kidneys ; 8. Structural diseases of the liver itself, such as fatty liver, may result from long continued derangement of its disintegrative functions ; 9. General tissue degenerations and constitutional diseases ; [probably acute rheumatism, erysipelas, and sometimes pyæmia, chlorosis, and some other forms of anæmia.] 10. Diarrhœa, and its opposite, constipation—intestinal hæmorrhage—hæmorrhoids ; 11. Jaundice, of which the following tabular view is given, though in a more extended form (pp. 96-98).
 A. Jaundice from mechanical obstruction of the bile-ducts ; *a.* By foreign bodies within it ; *b.* by inflammatory tumefaction of the duodenum or living membrane of the duct, with exudation into its interior ; *c.* Obstruction by stricture or obliteration of duct, from various causes (five enumerated) ; *d.* Obstruction by tumours, closing the orifice of the duct, or growing within it ; *e.* Pressure in the duct from without (ten causes mentioned, which may be reduced to four, viz., tumours and enlarged glands, aneurisms, pregnancy, fæcal accumulations).
 B. Jaundice independent of mechanical obstruction of the bile-ducts ; *a.* Poisons in the blood (fevers, animal, vegetable, and mineral poisons) ; *b.* Impaired or deranged innervation (shock, fright, anxiety, etc.) ; *c.* Deficient oxygenation of the blood ; *d.* Excessive secretion of bile, more of which is absorbed than can undergo the normal metamorphosis (congestion of the liver) ; *e.* Undue absorption of bile into the blood from habitual or protracted constipation.
 12. Numerous derangements of the nervous system, neuralgia, cramps, vertigo, convulsions, paralysis and coma, etc., and especially irritability of temper ; 13. Disturbances of circulation such as palpitation, pulsatile aorta, intermittent pulse, angina pectoris, and venous thromboses ; 14. Chronic bronchitis, spasmodic asthma, etc. ; 15. Eczema, lepra, psoriasis, lichen, urticaria, boils, carbuncles, xanthelasma (vitiigoidea) and pruritus are the chief skin-diseases attributed to liver-derangements.

Formidable as is this catalogue, almost as long as that of Homer's ships, and inclining one, if substantiated, to believe that 'Every disease is a disease of the liver,' Dr. Murchison has much that is pertinent to say on every one of these heads, and his own views on every subject are illustrated and supported, wherever possible, by illustrations drawn from the best British, American, and continental sources, both old and new ; some of the latter only published just before these lectures appeared. He inclines strongly to the view that liver-disease is often caused by mental and moral causes, and he writes eloquently against the abuse of alcoholic liquors which is so common in our days.

W. BATHURST WOODMAN, M.D.

MISCELLANY.

MISS ALICE VICKERY, the first and only registered lady pharmacist in England, has just passed honourably, in company with Mrs. Algernon Kingsford, the first year's examinations of the School of Medicine of the University of Paris.

MISS MARIA VOGTLIN, M.D., who graduated last spring in Zurich after a brilliantly sustained examination, has settled there as a practitioner in diseases of women and children, and has already obtained an extensive *clientèle*. She is now the wife of Dr. Heim, one of the professors in the faculty of medicine at Zurich.

YELLOW FEVER.—A somewhat remarkable circumstance has occurred in connection with the yellow fever in the Gulf cities of the South. It has hitherto been received as a certainty that upon the advent of frost the fever would disappear ; but this year it does not disappear, although there have been several frosts. In both Pensacola, Florida, and Mobile, Alabama, there still linger several cases of genuine yellow fever.

CAMBRIDGE PHILOSOPHICAL SOCIETY.—At the meeting of this Society on November 30, a paper on 'Lopsided Generations,' or 'Righthandedness,' by Dr. W. Ainslie Hollis, was read. The author laid special stress on the statement that the left side of the brain in man is the larger, and that aphasia is connected with disease of that side ; statements which, in the discussion which followed, Professor Paget justly remarked were not yet in any way proved. The cases of Johnson and Swift were quoted as instances in which the left side of the brain had suffered, and paralysis of the right side had been induced, apparently as a consequence of overwork. Professor Humphry and Mr. Carver both agreed that right-handedness was much a matter of education.

DOGMA *v.* SCIENCE.—Seven memoirs have been sent in to the Paris Académie de Médecine, in competition for the Capuron prize. They are on obstetric subjects, and the one which is expected to carry off the prize treats of uterine retroversion during pregnancy. The author has laid stress on the differences existing between a sacciform bag of the posterior wall of the uterus, which forces the neck forward, and non-symptomatic retroversion, facts which have long been known. The author of the memoir recommends puncture of the bladder, a useless operation, which, M. Depaul remarks, is of no avail as a remedial measure, whilst premature delivery may save the mother and sometimes the child also. According to the *Journal des Connaissances Médicales*, M. Bernutz explains that the author of the memoir in question is a professor at the Catholic University of Louvain, and he would have been reprimanded and placed in the Index if he had mentioned the existence of the operation for premature labour, which is rejected by his school, in opposition to what is permitted in Italy, and even in Rome itself.

COMPARATIVE EFFECTS OF SEA AND MOUNTAIN-AIR. Professor Beneke, of Marburg, makes some observations in the *Deutsches Archiv für Klinische Medizin*, March, 1874, on the comparative influence of sea and mountain-air on the system. He believes that he has ascertained experimentally that bodies part with their heat much more rapidly on the sea-coast than on mountain heights. This explains why it is that metamorphosis proceeds more rapidly at the sea-side than elsewhere, and that an increased amount of urea and a diminished quantity of uric acid and earthy phosphates are met with in the urine. The increased abstraction of caloric makes an increased production necessary, and accordingly leads to greater rapidity of metamorphosis. If these observations are verified, Beneke points out that we will have a much more definite indication for the recommendation of particular climatic changes. As the increased metamorphosis depends, *ceteris paribus*,

on the rapidity with which heat is abstracted from the body, it follows that, in mountain-air, the processes of change will be less considerable than at the sea-side. Accordingly irritable, nervous, excitable people, will find themselves better in mountain-air; on the other hand, scrofulous subjects, and persons with good digestive organs, who have been overworked, will derive greater benefit from a sojourn at the sea-side. The diminished atmospheric pressure at considerable elevations is also of importance, both by rendering bodily movements easier, and by increasing the activity of the respiratory movements. In making his observations, Beneke was careful to exclude every source of error, such as might be caused by difference of temperature, moisture, and winds, and he can only refer the remarkable differences which he has observed to the diminished density of mountain-air making it a worse conductor of heat.

OPHTHALMOLOGY IN SPAIN.—It well known that the inhabitants of warm climates are liable in a special degree to diseases of the eye and its appendages, brought about by the combination of the effects of burning sunlight, with hot dry winds and an atmosphere charged with sand or dust. In Egypt all these conditions are met with in the highest perfection, and when we add to these natural conditions a superstitious belief on the part of the inhabitants that it is wrong to attempt a cure of such complaints, we need not wonder that the country in question should be considered as the home of many varieties of such diseases. To a less extent, but in a very high degree, the same conditions of climate and of atmosphere are met with in Spain; and Dr. Camuset, in an article in the *Gazette des Hôpitaux* for September 24, draws a striking picture of the conditions which exist in the large towns of Andalusia, for instance; the glare from the whitewashed walls is intensely painful, necessitating a shade for the eyes, or in many instances the use of protective glasses which carry with them an inherent evil of their own, in that they induce a degree of sensitiveness to light for some time after their use has been discontinued, an effect which is overlooked by many who are in the habit of prescribing them. The number of blind people to be met with in Spain is a fact which at once forces itself upon the attention of the traveller; and in the condition of the climate, and in the ignorance and superstition of the inhabitants, the explanation is not far to seek. Blind beggars patrol the streets in bands, the majority of whom appear to have suffered from the corneal opacities and the varieties of staphyloma, which are the result of neglected ophthalmia incurred in infancy. On the other hand, amaurosis and other deep-seated causes of blindness are rarely met with. Amongst other diseases of the eye which are very commonly to be met with, are diseases of the lachrymal organs in every variety and in great numbers. Cataracts are common, and so also are corneal affections of a scrofulous type, and such as have their origin in want of proper food, and in general neglect; affections of the retina and atrophy of the optic nerves are rarely seen. All this, however, it is hoped, belongs to the past. Most of the large towns in Spain can now boast of their well-educated teacher, brought up in the French medical schools; and in many there are well appointed ophthalmic clinics. At Barcelona, for instance, Drs. Osio, Torrès and Carrera are at the head of well-attended clinics upon the French model. At Valencia, Dr. Armet, Professor at the School of Medicine, and Dr. Aparicio practise ophthalmic surgery with success. Dr. Camuset describes a case which he saw in the practice of the last-named surgeon. The case was that of a man who, during a fainting fit, had fallen with his head upon a burning brazier. The skin of the face was severely burnt, and the eyelids were completely destroyed. The injury was so extensive that there was no possibility of separating the eyelids from the integument of any part of the face. They were, however, replaced from the integument of the patient's arms with very great success. Seville has its ophthalmic surgeon in Dr. Chiralt; and at Cadiz there is a public hospital under the direction

of Dr. Toro. At Madrid the science of ophthalmology is taught and practised by Drs. Cervera and Delgado. The former of these gentlemen, a distinguished assistant for many years of the elder Desmarres, presides over a public hospital which is under the management of the Society of Saint Vincent de Paul, and is attached to the college of Saint Isabel. Dr. Cervera still gives his allegiance to the old method of Daviel for extraction of cataract, and he frequently destroys the lachrymal sac for long-standing disease. Dr. Delgado, another assistant of Desmarres, established a private clinique in 1860, the importance of which was soon recognised, and the municipality charged itself with its support, and in 1872 King Amadeus and his queen became its patrons, and added new buildings, so that there now exists a flourishing institution, which affords aid to a large number of patients, and where a large class of students are annually educated. The arrangements for teaching in all its different directions, and for the treatment of large numbers of patients, both as indoor and as outdoor patients are elaborate and complete, and could hardly be excelled by any such arrangements for the purpose in any other schools. There is a museum with a liberal supply of good microscopes; outpatient's rooms have been most carefully fitted up with all appliances; and there is an operating theatre which cannot, says Dr. Camuset, be excelled anywhere. In this theatre, Dr. Delgado performs about 600 operations annually, 250 of which are for cataract. The nursing is under the control of ladies of the Society of Saint Vincent de Paul, the lady superintendent of whom is French. The institution, since the abdication of its royal patrons, has the support of the marshal president, and is justly regarded as the Alma Mater of all students of ophthalmology in Spain.

DAVIES'S EFFERVESCENT SALTS.

Mr. M. N. Davies, of Tenby, has introduced a series of effervescing salts, which are intended to serve as portable substitutes for the waters of the alkaline, sulphurous, and chalybeate spas. They are of three kinds, an alkaline effervescing salt, a sulphurous effervescing salt, and a chalybeate effervescing salt. All of these salts are well worthy of professional attention. We know none which are superior to them, and they possess several unique advantages, especially that of becoming alkaline during effervescence, owing to an act of double decomposition.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17s. 4d.; free by post, 19s. 6d.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & Co., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The First Volume, containing upwards of Two Thousand Articles abstracted and compiled by a staff of Fifty Hospital Surgeons and Physicians, is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for the year 1873 are also ready, price 1s. 6d. each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & Co.—Calcutta: THACKER, SPINK & Co.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & Co.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & Co., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, DECEMBER 30, 1874.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

TREATMENT OF PULMONARY PHTHISIS. By PROFESSOR BEHIER.*

The treatment of this disease should in truth begin, if it be possible, before the malady itself is an evident fact; this, indeed, should be so whenever we are called upon to treat an organic lesion; it is necessary to attempt the cure of the disease before its reality is demonstrated, and as soon as there is reason to fear the development of an evil, which at a later stage will be obstinate, if not irremediable. In no case is the Horatian precept *Principiis obsta*—always excellent—of greater value.

Prophylaxis has then here, perhaps, more essential importance than in any other case. But the measures to be taken are, above all things, individual in their character, and must arise out of the study of each patient in particular; for according as such or such a tendency manifests itself, such or such a course must be adopted. I shall give here then especially general indications; and the first, which is of general application, is, not to fall into exaggeration of whatever kind. Every day, indeed, we see prescribed for certain delicate individuals, infants or adults, a hygiene rather violent in its character, destined to harden them and to render them less vulnerable; they are clothed as lightly as possible; they are made to go out as soon as possible, and are deprived of all the usual precautions. This is playing with danger, and there is here an useless and dangerous precaution. In other cases precautions are multiplied; the suspected person, infant or adult, is surrounded with exaggerated care; shut into places which have always a high temperature, and covered with warm clothing; kept from the pure outer air for fear of the least chill; and thus the economy of the body is weakened, and withers away under the very influences which were intended to save it from that result.

Avoid these exaggerations. Seek especially a moderate temperature; do not fear the open air; prescribe it, on the contrary, but only when the air is gentle, and without abrupt changes. These general precepts ought also to guide us in the choice of climate which the individual whom we desire to save should inhabit. I shall presently insist further on this point when we study the question of the curative influence of climate. So for diet: let it be mixed; do not fall into that error which we observe often, and which consists in condemning persons who seem disposed to be phthisical to the continuous and exclusive use of red meat (beef, mutton, etc.), eaten when half cooked. This prescription does harm in the direction in which it aims at doing good, and

though the diet is tonic and restorative in the intention of those who advise it, it has not that effect in reality, because satiety engenders anorexia and disgust, and diarrhoea even is likely to supervene in individuals who conscientiously endeavour to conquer their repugnance. Allow them a mixed *régime*, from which, however, you must exclude acid things which are eaten hard and raw, and too great quantities of fruit; in a word, every excess of food capable of producing diarrhoea, and every aliment which does not agree with the patient.

As to drinks, you need not fear the moderate use of wine or brandy. But remark that I say the moderate use, which imposes on you the necessity of watching that every excess be avoided. The use of tobacco must be formally proscribed always as bad; whatever may be said about it, this habit is especially calamitous to persons threatened with pulmonary phthisis. Excess of venery and masturbation are both much to be dreaded, and the latter has, in some cases, a directly etiological influence. Observe also that every individual who appears to be threatened should carefully avoid late hours, whether for the purpose of work or of pleasure. All excessive expenditure of force is injurious to such persons, and a reparative sleep, sufficiently prolonged, is among the most indispensable necessities. Unfortunately these precautions are often only temporarily efficacious, or they are forgotten, and the disease declares and develops itself.

Then commences the veritable treatment. To what means must we have recourse? For long, and even now, the means of specific treatment have been the object of research. Do not put faith in their existence.

Without pretending to the discovery of specifics, certain medicines have been brought forward as being endowed with well-established efficacy. The list of the agents so recommended is very considerable. I shall pass over those which are chiefly useful to the persons who invent them and profit by their sale, and speak only of those which are free from danger and serve as resources more or less useful in the cause of lingering disease; and first of all of tartarised antimony.

Sylvius de la Boë attributed to this medicine an alternative action in general disorders (*De Methodo Medendi*, lib. ii. cap. x.). Huxham, Cheyne, Rivière, expressed a more or less analogous opinion: but, however, it was especially as an evacuant that these authors employed tartarised antimony, whilst Thomas Read, with the same object, preferred ipecacuanha. Lanthois (*Thèse Nouvelle de la Phthisie pulmonaire*, Paris, 1815) preferred tartarised antimony in the dose of 5·7 or 10 centigrammes in eight pints of pure water, or of a strong decoction of colt's-foot, as the habitual drink of the patient. He thought that this subtle agent was capable of penetrating into the corners of the system, increasing the strength, aiding the digestion, agitating and dissolving the degenerate juices, etc. [Passing over other early references we come to] M. Fonsagrives in 1860, who published an interesting memoir on the use of tartarised antimony (*Bulletin Gen. de Thérapeutique*, vol. lix. 1860, p. 5) in the febrile form of phthisis. His form is as follows: water 120·0, tartarised antimony 0·2, syrup of diacodium (a syrup of laudanum) 15·0, laurel-water 2·0, syrup of orange-flower water 15·0. This draught is administered by teaspoonfuls, one every hour, or every two hours if the patient be not very tolerant of the medicine. The addition of opium,

* Extract from a Clinical Lecture at the Hôtel Dieu, August, 1874. *Bulletin de Thérapeutique*, November 30.

M. Fonssagrives insists, formed part of the habitual mode of using antimony in such cases, introduced by Laennec into common use. M. Fonssagrives aims at procuring tolerance, and does not proscribe food. The antimony should at first not be administered for the space of an hour before or after food. The diet should consist at first of light soups. Subsequently the quantity and quality of the food may be gradually increased. At the end of a week solid diet may generally be adopted, and the patient thus supports better the antimonial treatment. Under its influence, it is said, the sweats and the dyspnoea evidently decrease, the expectoration becomes less and more easy, and there is no diarrhoea.

The total dose of tartar emetic absorbed would be 8 to 10 grammes, in the course of from one month and a half, to three months. This treatment, exceptionally useful, according to this author, in the first stage of phthisis, would be adopted by preference and with great advantage in the third, except when the patient presents the smooth and shining state of the tongue deprived of epithelium, the epigastric sensibility, signs of an approaching end, and of pulpy softening of the gastro-intestinal mucous membrane.

To facilitate the tolerance of antimony, M. Fonssagrives has varied a little his formula, and has replaced the laurel-water, for example, and the syrup of orange-flowers, by fifteen grammes of syrup of gentian and one gramme of tincture of quassia. To render the dose more sedative in cases where the fever is more obstinate, he adds to tartarised antimony, or preparation of opium, which he employs always in the same doses, two granules of digitaline, with or without a bitter, and still in 120 grammes of the vehicle. Finally, M. Fonssagrives insists of the necessity which has long been recognised of making the patient gargle with strictness, and wash the lips after each antimonial draught.

After having employed this treatment, I remain without much enthusiasm for it as a general treatment of cases of phthisis without fever. In the first place I do not believe that tolerance is so easily obtained as he seems to think. In many cases tartarised antimony in four-grain doses, taken as M. Fonssagrives recommends, excites vomiting, and finally diarrhoea. I have even seen it produce real poisoning and death. Nor do I think that the strength is regained so evidently under the influence of this method. We shall, however, presently find that in certain complications of phthisis this agent is clearly indicated, especially as indicated by Fodéré, in combatting bronchitis, catarrh, and those pulmonary congestions which occur in pulmonary phthisis, and hasten its fatal march.

ON THE PARALYSIS OF CHILDREN ACQUIRED DURING DELIVERY. By DR. SEELIGMÜLLER, OF HALLE. *

(Concluded from page 803.)

Dr. Seeligmüller relates six cases personally observed by him. [The narratives are abridged.]

Case 1. *Inter partum paralysis of both arms without complications, after difficult extraction with turning.*—Dr. Fritsch, under whom the woman was delivered, stated that the pelvis of the mother, who

was a primipara, was universally small. The head was extracted with much difficulty after a delay of about ten minutes. Both arms were paralysed; no separation of the epiphyses nor fractures were discoverable. Laceration of the brachial plexus was diagnosed. When seen by the writer at the end of the fourth week, the child was strongly developed; it had almost complete paralysis of both arms. A trace of movement could be observed in the right arm, but it was very limited. Both arms were strongly rotated inwards, the hands in extreme pronation, with the wrist-joints bent and directed towards the ulnar. In the right arm, faradaic excitability was reduced, but not entirely gone; in the left upper extremity from the shoulder to the hand, it was *nil*. The extensors and flexors of the left forearm were only excited by a strong, continuous current of forty large elements of the Siemens-Halske instrument. The child was locally faradised two or three times a week; and the mother was directed to make passive rotation of the upper arm. A perceptible improvement did not take place until very late; a positive amelioration only at the end of five months; the left arm was now found not atrophied when compared with the right. Only very slight inward rotation was present; the extensors of the left forearm were excited by the faradaic current, although not so strongly as the right; and the child, when given a stick, could hold it in the usual way.

Case 2. *Inter partum paralysis of the right arm complicated with fracture of the neck of the scapula and the clavicle.*—Professor R. Volkmann transferred the case for electrical treatment at the ninth month, with the diagnosis of paralysis of the right arm, in consequence of fracture of the neck of scapula and the clavicle (*inter partum*). The medical man stated that, as far as he could remember, it was a very rapid breech-case, the pains being exceeding strong; the arms were delivered as usual. The right hand was felt along side of the knee, and hanging down in the pelvis; it was at birth considerably red and swollen. The nurse did not observe that the arm was powerless for some time, and still later found a fracture of the clavicle. The older the child grew, the more marked became the paralysis. When first seen, distinct movement between the body of the scapula and the head of the humerus could be made out, with slight shortening of the clavicle, and a circumscribed thickened spot in the middle of this bone. The only movement the patient could make with the arm was a slight elevation of the shoulder-joint; with this uplifting the arm was rotated still more inwards and adducted; the child had the habit of moving the arm towards the mouth. The fingers were slightly flexed, but no movement in them had been noticed. The most remarkable thing was that the right arm was at least as large as the left, its length the same; the temperature to the touch seemed equal in both arms. The extensor and interossei muscles of the right forearm were not excited by the continuous current, even when very strong; the excitability of the flexor muscles was much diminished, also that of the muscles of the upper arm in a less degree. The shoulder-muscles, especially the deltoid and trapezius, were of normal excitability. No contraction could be produced by the continuous current, in the muscles of the forearm, not even of the flexors. The patient could bear with impunity the strongest secondary induction-current on both sides of the forearm, hands and fingers, even till sparks flew across; but the moment

* *Berliner Klinische Wochenschrift*, October 5 and 12, 1874.

a second weaker current was applied to the region of the deltoid or shoulder he cried out. An affection of the cervical sympathetic nerve was observed by the writer in this child, and published in the *Berliner Klinische Wochenschrift*, 1870, no. 26.

After a very unsatisfactory course of faradisation, considerable improvement in the condition of the child was effected. The upper arm was rotated more outwards, the fingers could move somewhat, and the hand which, from the inward rotation of the arm, was helpless, could now hold a stick firmly when placed in it. The sensibility had improved, and the application of a moderately strong secondary induction-current upon the palm caused the child to cry out. The faradaic excitability of the muscles of the forearm and of the extensors had improved. Reflex movements by tickling the hollow of the hand could not be produced. The child was now removed away for treatment.

Case 3. *Inter partium paralysis of the left arm, in the beginning most likely of the facial nerve also, complicated with fracture of the left clavicle.*—The child was a third one. The head was born some time before the shoulders could be delivered, and the midwife brought down the arms. On the third day swelling of the left shoulder was discovered, as also of the left half of the face, which remained thicker, redder, and warmer than the right. The left ear was not observed; the mouth was drawn to the right, and the left nostril lengthened, and smaller than the right; the tongue was affected, and the saliva dribbled from the right side of the mouth; the head, which was inclined to the right, at the end of about three months gradually recovered itself; the left shoulder remained deformed; the arm atrophied, and its growth was arrested, and it could move but slightly. Professor R. Volkmann, on sending the case to Dr. Seeligmüller, stated that the left cheek was larger than the right, the left half of the thorax was less developed than the right (the nipple was lower down), the left clavicle was shorter, with the remains of a callosity on it about one to two inches from the top of the acromion. The left arm was much atrophied, flexed at the elbow, and lying flaccid alongside of the trunk. At the shoulder-joint there were only the slightest movements perceptible of the arm forwards, backwards, and outwards; the fingers were flexed and distinctly movable; the nails on the left hand were long, but normal; the whole of the left hand and the thumb were arrested in growth. The left lower extremity was normal. With faradaic excitation, for a certainty, only the flexors of the forearm contracted; with galvanism not even these. The child was one year old when first seen; when next seen at the end of four and a-half years the paralysis of the arm and its accompanying phenomena are more marked; the deformity of the shoulder was worse. The clavicle was 0.4 inch shorter than the right. The thickened point of fracture formed an angle looking upwards and outwards. The left half of the chest was considerably smaller and was deformed, besides which, the growth of the scapula was arrested, and its spine was 1.2 inch shorter than its opposite. The whole of the upper extremity was extremely atrophied, and all its bones were arrested. The deltoid had entirely disappeared, the biceps and brachialis were a mere cord. On the dorsal side of the forearm the flesh could barely be felt. The elbow-joint could only be extended to an obtuse angle, and bent to a right angle, apparently from some obstruction in the joint itself; its exact nature could not be made out. The whole

joint seemed thickened, the limb felt colder than the other. The nails were well grown. The patient could bend the forearm actively on the upper arm to a right angle; a stretching of the remainder of the flexors could be distinctly felt. The ability to elevate the shoulder was *nil*. The arm and hand could be with difficulty moved behind the hips, but it could bear comparatively a considerable weight. There was still a trace of the facial paralysis at the angle of the mouth. It was a remarkably healthy and intelligent child.

Case 4. *Inter partium paralysis of both upper extremities complicated with luxation of the head of the radius and ankylosis of both shoulder-joints.*—The child, five and a half years old, was transferred to Dr. Seeligmüller by Professor R. Volkmann for electrical treatment. The labour was said to be difficult; it was a cross-birth with prolapse of the arms; after turning, there was some trouble in getting the arms down; as soon as born, it seems that both arms hung down powerless by the side, and when placed to the breast they fell over the child's head. The crippling of the hands was observed soon after birth. The child, although small, was quite healthy and very intelligent. The right hand was turned acutely towards the ulnar side and flexed on the forearm; the fingers were moderately flexed and crooked towards the radius. Neither the wrist nor the fingers could be extended, but passively it could be done easily on account of their excessive flaccidity; if placed on a splint for long, they would for a time retain their right position when taken out of it. The ulnar position of the wrist-joint was produced by the complete paralysis of the extensor carpi radialis which was not excited by the most powerful faradaic current, whereas the excitability of the extensor digitorum communis and the extensor carpi ulnaris was reduced. The flexors of the forearm reacted the best. The left hand was still more deformed. The ordinary position of the arm was between the prone and supine, arising from the luxation of the head of the radius; the wrist was slightly flexed, the hand stood like a claw, and was with difficulty straightened; the thumb was exceedingly hooked, and appeared like a mere appendage. The left arm was the weaker of the two. The sensibility of the left hand was considerably reduced—of the right, less so; still it could receive a tolerably strong current without crying. The faradaic excitability in the muscles of the shoulder and upper arm on both sides was reduced. There existed a certain difficulty in movement in the shoulder-joint, which prevented any passive movement backward, and permitted only the slightest possible passive movements in other directions. The electro-cutaneous sensibility of the shoulder and upper arm seemed normal. The excitability of the muscles of the forearm, with the exception of the flexors, which were slightly excitable, was *nil*. The biceps showed no signs of reaction, the triceps only a trace. The galvano-muscular excitability was to a certain extent diminished in all the muscles. The enforced rest of the shoulder-joint, and consequently of the shoulder-blades, expressed the relative smallness of the latter. A long-continued faradisation produced no benefit.

Case 5. *Inter partium paralysis of the left shoulder, complicated with fracture of the lower portion of the scapula.*—The patient, a girl, was fifteen years old when referred by Professor R. Volkmann to the author. She presented extreme deformity of the left

shoulder, which was observed soon after her birth. She was a tall, thin, and pale-looking girl, with deformity of the whole of the back. The left shoulder-blade had a remarkable appearance; the superior internal angle of the scapula was elevated above the left shoulder line, whilst the internal border ran obliquely to the spine; the inferior internal angle nearly touching the spinous processes. The left scapula was much smaller than its fellow, the fossa infrascapula was distinctly curved concavely outwards; obliquely across it was felt a ridge, which evidently represented the parts fractured *inter partum*. The left upper extremity was less developed than the other. Various movements were possible with the left arm, but less prompt and energetic than with the right. The right shoulder-blade was of normal size and shape, but stood out somewhat funnel-shaped from the thorax. This deformity yielded considerably during the six months' treatment. The muscles of the left shoulder-blade, from the long continuance of their abnormal position, had lost their function of contractility, so that the strongest faradaic current was unable to excite some of them; the most that could be done to improve the position was by exciting the *teres major*.

Case 6.—*Fracture of neck of the scapula with luxation of the head of the humerus backwards*.—The child was three and a-half years old when seen. Its right upper arm was broken *inter partum*, whilst delivering the arms, turning being requisite on account of cross-birth. There was considerable movement of the arm, but inability to move it backwards or above an angle of 45° forwards. The faradaic contractility of the muscles was retained. The right arm was shorter than the left.

W. C. GRIGG, M.D.

DR. SEGUIN ON THE PHYSIOLOGY AND PATHOLOGY OF THE NERVOUS SYSTEM.

Dr. Seguin (*New York Medical Record*, Dec. 1), sums up an able outline of the physiology of the nervous system in the following propositions.

There are four generalised functions in the nervous system.

1. Sensation and perception are executed by means of paths which decussate almost horizontally in the spinal axis; the conduction being by the gray matter, not by the white columns of the cord; coarse sensibility with doubtful consciousness has its seat in the pons Varolii; perfect perception and appreciation is possible only with the help of the cerebral mass.

2. Motion is executed through motor impulses, which, starting from the opto-striate bodies (from cortex of cerebrum also?) traverse paths which decussate almost opposite the motor nerves as far down as the lower margin of the medulla oblongata, where the paths for the trunk and limbs decussate in a bundle, to remain, below this point, in that half of the spinal cord whence arise the nerves going to the muscles.

3. Reflex action is the result of a transformation of an irritation from the periphery into nervous force by a nerve-cell, transmitted centrifugally by a second nerve. That all nervous phenomena are of reflex mechanism, is not to be too positively denied.

4. Co-ordination is no faculty, but a function of every portion of the motor tract of the spinal axis from the origin of the third cerebral nerve down.

There are a few pathological laws logically allied

to the physiological propositions enumerated above, which I wish to submit.

1. Any disease of any part of the nervous centres may produce two kinds of symptoms, which we should always attempt to distinguish, these being symptoms of irritation, consisting, according to the location of the lesion, in exaltation of ideas, delirium, in numbness, pain, and in spasmodic movements; and symptoms of destruction of parts, loss of mental power, anæsthesia, paralysis. Brown-Séquard was, I believe, the first to insist upon the exceeding importance of distinguishing these two classes of effects.

2. It should be borne in mind that irritating lesions may cause the second class of symptoms by producing an inhibitory (arresting) effect upon centres near or distant.

3. Ischæmia of the nervous centres produces extreme irritation symptoms, delirium, spasms, pain, and numbness, followed by loss of function of parts.

4. The effects of hyperæmia are not satisfactorily known.

5. A want of equilibrium in the circulation of both hemispheres is a common cause of vertigo.

6. Almost any lesion of the nervous centres may disturb the nutrition of distant (non-nervous) tissues.

7. A generalised lesion of the convolutions of the brain produces, first, exaltation of mind and emotions, followed by abolition of the faculties, and a false general paralysis.

8. A lesion of one cerebral hemisphere gives rise to symptoms (paralysis, numbness) in the opposite side of the body and face. The localisation of the lesion in the left hemisphere about the fissure of Sylvius, is exceedingly likely to abolish language spoken and written; while lesions of the right hemisphere produce more severe palsy, set the emotions free, and endanger life more.

9. A lesion of the centre of the pons Varolii will produce general paralysis, with probably anæsthesia and changes in the bottom of the eyes.

10. A lesion in one-half of the pons Varolii will produce palsy with (probably) anæsthesia in the opposite side of the body.

11. Lesions of the cerebellum when in one lobe produce an incomplete hemiplegia on the opposite side, with marked eye and stomach symptoms.

12. A suddenly produced lesion of the centre of the medulla oblongata will probably kill the patient at once by arresting respiration.

13. A lesion localised in one-half of the medulla oblongata will give rise to hemiplegia and anæsthesia on the opposite side.

14. A lesion at the base of the brain, not on the median line, will produce a crossed palsy (as first indicated by Romberg); palsy of the body on the side opposite the lesion, and palsy of one or more cranial nerves on the same side as the disease.

15. Pressure anywhere within the skull may affect the nutrition of the optic nerves.

16. In lesions of the cerebral hemispheres accompanied by coma (apoplexy), the eyes are together turned and fixed towards the side of the lesion, and away from the palsied side.

17. A lesion occupying the whole thickness of the spinal cord, or its grey matter, will give rise to palsy of all parts below the lesion, *i.e.*, below the distribution of nerves issuing from just above the lesion; and such a paraplegia is necessarily attended by anæsthesia, and increased reflex movements in palsied parts.

18. A lesion in one-half of the spinal cord (hemisection, Brown-Séquard), at any point will produce paralysis with hyperæsthesia on the same side as the lesion, and anæsthesia on the opposite side.

19. A lesion involving the posterior columns of the spinal cord produces neuralgia and ataxia of movements.

20. A lesion affecting the lateral columns of the spinal cord will cause a paralysis accompanied by contracture.

21. A lesion of the cells of the anterior horns of the cord alone will produce a palsy (no anæsthesia), accompanied by extreme wasting of muscles, and loss of electro-muscular reaction. Any part of the spinal axis may be the seat of this disease.

22. A lesion (destructive) of nerve-trunks gives rise to a paralysis with anæsthesia, and rapid loss of electro-muscular reaction.

23. A lesion in the cerebrum and the opto-striate bodies may produce secondary lesions in the spinal cord and nerves.

24. A lesion of the spinal cord may cause secondary lesions upward and downward in the cord, and in nerves.

25. Lesions of nerve-trunks may produce secondary lesions of the spinal cord.

ANATOMY AND PHYSIOLOGY.

THOMA ON THE INFLUENCE OF THE CONCENTRATION OF THE BLOOD AND TISSUE-JUICES ON THE CHANGES OF FORM AND PLACE OF THE COLOURLESS BLOOD-CORPUSCLES.—R. Thoma (*Virchow's Archiv*, vol. lxii. Heft 1), has made investigations on this subject.

1. *Influence of the Concentration of the Surrounding Fluid on the Amœboid Movements of the Colourless Blood-Corpuscles removed from the Body.*—Blood of the frog, placed in a gas-chamber, and from which water was removed by the passage through it of a stream of air, showed that, in the portion of blood poor in water, the number of round motionless colourless corpuscles surpassed considerably the number of those showing changes of form. In blood in which the quantity of water was increased, the greater number of the colourless corpuscles showed the branched forms, such as are produced by the flowing movement of protoplasm. Those corpuscles which adhere to the cover-glass are more spread out, show clearly three or four nuclei, and bear more richly branched processes, oftener contain vacuoles, and show more lively changes of form than those floating free in the fluid. This is, without doubt, due to the action of the surface, and is produced by strong adhesion of the body of the cell to the surface of the glass. This property also belongs to a series of other solid bodies, and also to the intima of the vessels. The white blood-corpuscles become more sluggish in their changes of form with increase in the concentration of the fluid, and the greater number change into rounded cells, which sometimes have fine processes on their surface. This is not due to death of the corpuscles, for on increase in the quantity of water they again become lively in their movements, and resume the properties of freshly drawn white blood-corpuscles. These observations were made in the blood of *Rana temporaria* and *esculenta*; but the same is also true for that of *Salamandra maculosa* and *Triton cristatus*, and

also for that of warm-blooded animals; at least for the guinea-pig and dog. Under the influence of water, the contents of the white corpuscles may be increased four times, and this can only be regarded as an imbibition phenomenon.

2. *Experiments on Colourless Corpuscles circulating in the Blood*, produced by injection of water into the circulation of the frog.—Besides unchanged colourless corpuscles, there are a large number which show forms such as can be produced in blood under the influence of water outside the body. Those which lie upon the walls of the vessels exhibit very lively changes of form. In an opposite experiment, frogs were exposed for several days to evaporation. Microscopic observation showed that in the tongue, under these conditions, no amœboid movements were to be observed in the corpuscles circulating in the blood, and also in those touching the walls of the vessels; and the injection of a 3 per cent. solution of common salt into the veins showed that increase of the quantity of salts acted quite in a similar manner to the regular concentration of the blood by the evaporation of water from the surface of the skin.

3. *Experiments on the Wandering Cells in Living Tissues.*—The question was, whether colourless corpuscles which have wandered outside the vessels are influenced in a similar manner by differences in concentration of the tissue-fluids. The cells which have wandered out into the tissue shows the lively amœboid changes of form and place, whilst, by infusion of a 3 per cent. salt solution and evaporation from the skin, the amœboid movements of the wandering cells become slower and very soon cease altogether. The same was observed with a 1.5 per cent. solution, the colourless corpuscles becoming round and shining, and changes of place could no longer be observed of them; whilst with a 0.5 per cent. solution the changes both of form and place were very lively. Irrigation of the frog's tongue with salt solution of various strengths also produced important changes in the calibre of the blood-vessels, and therefore on the rapidity of the blood-current. Under irrigation by a 0.5 per cent. solution, a very plentiful out-wandering, specially from the small veins, takes place, while in the same organ with a 1.5 per cent. solution, the wandering out of the colourless corpuscles is completely suppressed. This solution acts first on the blood-vessels, producing a pronounced dilatation of the arteries, and therewith an acceleration of the blood-current in the arteries, capillaries and veins, as Wharton Jones had already proved, and which, as H. Weber, F. Schuler, Buchheim, Vierordt, etc., showed, depends essentially on the diffusion of the blood-plasma with the salt solution. The acceleration of the blood-current is so considerable, that the venous current takes on part of the characteristics of the arterial one. Specially, the marginal position of the colourless corpuscles disappears. The second effect of the 1.5 per cent. solution of common salt is its influence on the changes of form and place of the colourless corpuscles.

The chief results of this investigation are, first, that changes in the quantity of the salts and the concentration of the blood and tissue-juices, within those limits which are compatible with the existence of the animal organism, exercise a powerful directing influence on the changes of form and place of the colourless corpuscles. Concentration of the tissue juices causes these corpuscles to lose their property of changing their form and place, so that they be-

come round and shining. These phenomena may last for days, until a dilution of the tissue-juice is again produced, when the lively changes of form and place of the corpuscles begin again. Thus they show a tolerably wide similarity with vegetable protoplasm, as pointed out by Kühne on the *Myxomycetæ*.

Secondly, it is proved that the wandering out of colourless corpuscles from the vessels of the frog's tongue, in spite of a large loss of substance, can be completely hindered by the irrigation of the wound with a 1·5 per cent. solution of common salt, that it is hindered by the thickening and increase of the salts of the blood. By irrigation with salt solution, of the above concentration, the action depends upon the acceleration of the rapidity of the current caused by the continuing dilatation of the arteries, and on the direct influence upon the protoplasm of the colourless corpuscles of the blood. The acceleration of the venous current prevents the marginal position of the colourless corpuscles, and in this way extinguishes the first condition for the out-wandering of the same from the veins. The influence of a 1·5 per cent. solution of common salt stops, during the irrigation, change of form of the protoplasm of the colourless corpuscles, and simultaneously their out-wandering from the vessels, and every obvious change of place in the tissues.

W. STIRLING, D.Sc., M.B.

MAYER ON DIRECT ELECTRIC EXCITATION OF THE HEART IN MAMMALS.—In a recent communication to the Vienna Academy (*Sitzungsberichte*, Band lxviii., 1 to 3 Hefte), M. Sigmund Mayer gives details of his experiments on this subject (which had been previously studied by Einbrodt and some others). The animals experimented with were dogs and cats; they were curarised, and arrangements were made for artificial respiration. As a rule, the thorax and pericardium were laid open, and the heart stimulated with currents; the electrodes being needles. For induction currents Du Bois-Reymond's apparatus was used, charged by two Daniell's elements.

On applying the electrodes, and pushing the distant secondary coil slowly towards the primary, the first effect, in the kymographic curve, is that the blood-pressure, at a certain not very great strength of current, suddenly sinks very low; it is at first like what occurs on strongly stimulating the vagus. Next, one is surprised to find the pressure, in many cases, show no sign of rising again, and that the elevations corresponding to heart-beats totally disappear; in short, that the animal, after stimulation for two or three minutes, with a moderate induction current, is dead. In the heart itself the contractions cease, and the muscular substance is thrown into an irregular rapid trembling; the heart swells and is found filled with dark red blood.

Now in the case of stimulation of the inhibitory fibres in the vagus, the cessation of the heart's motion is only for a few seconds; though the stimulation is continued, it begins again to beat rhythmically and strongly, and raises the blood-pressure; and after stimulation has ceased, the pressure further rises. There is none of the irregular trembling. Direct stimulation of the heart with induction-currents thus appears to act as a strong 'heart-poison,' in the case of animals which (as the above) have not been greatly altered by various operations (tying, curarising, loss of blood, etc.); whose temperature, especially,

has not been greatly lowered. In this other case, the phenomena are somewhat different. The weaker currents (of a duration of two to five minutes) may not prove fatal to the heart's action, but after stimulation ceases, the blood-pressure may rise again, the irregular tremblings combining into a normal systole; at certain points the trembling ceases, and a regular contraction is there observed. Thus, as the animals, by cooling, come nearer the condition of cold-blooded animals, there is the more reason to expect that the effects of direct stimulation will be counteracted.

The author next operated with constant currents. Between the battery (1 Grove, or 1 to 4 Daniell) and the electrodes, was inserted a Du Bois-Reymond-Sauerwald rheochord and a commutator. While M. Mayer's results with the induction-currents agree in the main with those of M. Einbrodt, they quite differ in the case of constant currents. On moving the steel slide of the rheochord from zero, the first action expresses itself, in the kymographic curve, as a sinking of the blood-pressure, along with irregularities and intermissions of the heart-beats; and is better seen on direct inspection of the heart. With a very weak continuous current, the previous heart-beats and blood-pressure soon return. On increasing the current, these phenomena are intensified, till at length, with a certain strength of current (not very great), the action of the constant currents and that of the induced currents correspond, that is, the constant current also calls forth the above described great disturbances in the co-ordination and power of the heart-contractions. This is quite in contradiction to M. Einbrodt, who finds the heart-motion at first more and more accelerated, the blood-pressure increased; this increase reaching a maximum, with increasing current, and diminishing (as the current is further increased), until, finally, the heart stops in diastole, and the animal dies. M. Mayer found no acceleration of the normal heart's action (the irregular contraction-waves could not be called normal heart-action), and no increase of pressure. And he points out that his method ensured that all values of the current from zero upwards should act. Further, Einbrodt's animals were not curarised, and the rise of pressure may have had other causes; and in one instance the pressure did not rise, but sank from 129 to 23·4 millimètres. The author thus cannot agree with Einbrodt's affirmation, that only constant currents of a certain strength are like induced currents in their action. He finds that induced and constant currents act alike, inasmuch as, on passing into a normally contracting heart, they produce intermissions in the heart-beats, and change the normal contractions into an irregular agitation (*Wogen und Wühlen*), which can no longer maintain a high pressure in the internal system. Thus, Einbrodt's proposed method 'for suddenly increasing the blood-pressure within no inconsiderable limits, by action of the heart alone,' viz., by stimulation with the constant current, can hardly prove successful. M. Mayer further found by experiment that stimulation of the inhibitory fibres of the vagus had no effect on the irregular motions produced by direct stimulation of the heart, and he hence also infers that this motion is different from the normal heart-contractions.

In accordance with his results, he dissuades from electric stimulation of the heart (when that organ is insufficiently active), as a very dangerous method.

In Steiner's experiments on electro-puncture, there was no guarantee that the heart was actually penetrated by the currents. What is permissible with other muscles cannot be applied to the heart-muscle, which morphologically and functionally occupies a distinct position by itself.

SERVEL ON GENERATION AND EVOLUTION OF BACTERIA IN ORGANIC TISSUES PROTECTED FROM CONTACT WITH AIR.—The author stated to the French Academy (*Comptes Rendus*, November 30) that his experiments were suggested by some ineffectual attempts he made to harden large fragments of cerebral substance with chromic acid. If the tissue be not treated in thin slices, the central parts of the piece, not being reached by the acid, undergo putrefaction.

In the five experiments now to be noticed, he used a solution of chromic acid, containing one part in 100.

The first two experiments were on guinea-pigs (in October, 1874). The live animals were decapitated so that the head fell at once into the chromic acid bath. In both cases, the results corresponded to those with the cerebral substance. Examined six days after immersion, the outer parts of the head were hard and preserved; but the central parts were in manifest corruption; under the microscope, the cerebral pulp presented a large number of bacteria of all sizes.

Feeling, however, that in these experiments the absence of air-germs was not sufficiently demonstrated, as the deep parts of the nasal fossæ or the buccal cavity might possibly have retained them notwithstanding the immersion, M. Servel repeated the experiment with the liver or kidney of dogs, killed for this purpose by femoral bleeding.

To eliminate sources of error, and especially entrance of air by the wound, he placed a ligature at the level of the hilum of the liver and the kidney to be experimented on; then he completely removed these organs, preserving their envelope of connective tissue throughout its extent. The threads of the ligature were used to suspend the organs and keep them from contact with the sides of the vessel containing the solution. This experiment, repeated three times (in October and November) on two hunting dogs and a shepherd's dog, gave the following results, after five days immersion (the average surrounding temperature being fifteen degrees). The liver and kidney were more voluminous than in the fresh state, elastic to pressure. The surface was hardened throughout, and gave the peculiar odour of organs immersed in chromic acid. On section, there was emanation of fetid odours. Under the microscope, the outer layer was found entire; the central parts were full of bacteria, showing characteristic movements; some, in the liver, were large, some enlarged at one end (*Bacterium capitatum*); in the kidney they were fewer, thinner, and more mixed with cells still intact. The solution of chromic acid at once arrested the movement of the bacteria.

Hence M. Servel concludes: 1. That MM. Bechamp and Estor's demonstration of the production and evolution of bacteria in organic tissues protected from air-germs is quite exact: 2. That the effect produced by preservative agents is the death of microzymes or molecular elements surviving in the organs.

PATHOLOGY.

ZAHN ON THROMBOSIS.—From his experiments and observations, Zahn (*Virchow's Archiv*, Band lxii. Heft 1, Nov., 1874) distinguishes thrombi into the red and the white. The former are produced by coagulation of the blood within the vessels; the latter would form the deposition and the gradual accumulation of colourless blood-corpuscles. Mechanical injuries, such as straining, tearing, or cutting, or chemical irritants, as ether, ammonia, croton oil, turpentine, and chloride of sodium applied to blood-vessels, lead to the formation of thrombi. The intensity and the duration of the injury, together with the previous condition of nutrition of the individual, determine the durability of the clot. The process of formation is the following. Colourless blood-corpuscles adhere to a part of the intima denuded by an injury of its endothelium. They accumulate there, form a ringlike obstruction, and gradually the clot obstructs the vessel altogether. If the injury be slight, and the nutrition of the individual unimpaired, the current of blood soon breaks through the blood-clot, and carries along the flakes of the colourless blood-corpuscles. The normal condition is soon restored. If the injury of the vessel be more severe, and the surrounding tissue already in a state of irritation, the thrombus, whilst forming in the same way as described, is firmer and larger. The obstruction is more complete, and lasts for twenty-four hours and more; after that period the thrombus begins to disintegrate into granular fibrine, the outlines of the blood-corpuscles composing the thrombus cease to be visible, and thus an uninterrupted circulation is re-established.

ZIELONKO ON HYPERTROPHY OF THE HEART.—Hypertrophy of the heart depends, according to Zielonko (*Virchow's Archiv*, Bd. lxii. Heft 1, November, 1874), upon the development of the young cells already present within the substance of the heart into muscular fibres, and probably also upon a new formation of them. The free-existing muscular fibres do not show an increase of their volumes. On the whole, the age, the general nutritive condition of an individual, together with local inflammatory processes, favour the development of hypertrophy of the heart, whilst the increased amount of work which the organ has to perform does not appear to have the same influence. Those changes also occur most frequently in youth, when the stimulus to the development of the organ is most powerful.

I. B. BERKART, M.D.

CAYLEY ON RENAL CALCULUS.—At a recent meeting of the Pathological Society of London, Dr. Cayley showed a renal calculus which was discharged through a fistulous opening in the loin. The patient is now thirty-three years of age, and in good health. Seven years ago he suffered from an abscess in the right lumbar region, which discharged for about three years. About six months after its formation, the calculus came out. It was of irregular club shape, the size of a hazel-nut, with a facet at the narrow end as if it had been broken off. Two smaller calculi subsequently ulcerated out, one close to the crest of the ilium, and one below the great trochanter, the scars still remaining.

MEDICINE.

BRUGELMANN AND KLINGELHÖFFER ON TRANSFUSION OF BLOOD.—The *Berliner Klinische Wochenschrift*, for August 24, 1874, contains a paper by Dr. Brügelmann of Cologne, on a case of phthisis cured by inhalation and transfusion of lamb's blood. A bookseller, W. L., aged thirty-three, slightly built, small and weak, had diarrhoea, night-sweats, cough, and loss of appetite. He had also catarrh of the stomach, brought on, it was supposed, from swallowing the expectoration. Inhalations of chlorate of potash and morphine were used with only partial benefit. On October 9, at 12.50 P.M., transfusion was performed with a May lamb. Before the operation the pulse was 100; temperature 37.4° Cent. (99.3° Fahr.). It was performed in the presence of Professor Max Müller and others. After thirty seconds the sight became affected; at the end of forty seconds the face was redder, and there was some perspiration, followed by redness of the extremities. Then came dyspnoea and cyanosis, with pains in the epigastrium; and, after eighty-five seconds, a feeling of faintness when the transfusion was stopped. The dyspnoea and cyanosis lasted ten or fifteen minutes after the transfusion was discontinued. At 1.12 P.M. came rigors lasting about an hour, with quick weak pulse. At 3.50 P.M. the pains had disappeared, and the patient asked for food. The colour of the skin was better than before the transfusion, and moist. October 10, the pulse was 106, temperature 38.8° Cent. (102.8° Fahr.), he felt stronger; the expectoration contained a little blood; the arm was painful; his appetite was improved, and his sleep good; there was no hæmaturia. On October 11, he was improving in every way. On November 20, he was able to take long walks and to work at his business. The cough and expectoration were less; he was gaining flesh. The pulse and temperature were normal. The improvement seemed to be aided by inhalations containing perchloride of iron.

The same journal contains an account of four cases of transfusion, contributed by Dr. Klingelhöffer, physician to St. Rochus Hospital, Mayence.

The first was a case of mediate transfusion with defibrinated human blood. H. A., aged thirty-nine, a merchant of Mayence, had ulcers of the stomach and symptoms of phthisis, with hæmoptysis or hæmatemesis, or both, and bloody stools. He being reduced to a great state of weakness, transfusion was proposed. On April 16, at 7 P.M., the blood (about twelve ounces) was taken from a strong man, aged between thirty and forty, and, after being defibrinated, was transfused into the median vein of the patient's right arm. During transfusion, he became warmer and the pulse stronger. The colour of the skin reddened, and there was free perspiration. An hour and a half later, there was a distinct shivering fit, with oppressed breathing, which soon passed off. In another two hours he appeared pretty well. On April 17, he slept well and felt better. The pulse and temperature were normal. On April 19, he was apparently doing well. On the 20th, he had numerous bloody stools; and on the 21st he died suddenly. *Post mortem* examination revealed extensive disease of the lungs, liver, stomach, and intestinal canal.

The second was a case of direct transfusion with lamb's blood. R. W., aged twenty-seven, had caries

of the bones of the arm, which was amputated. He then had abscesses and general cachexia (probably pyæmia), and was reduced to a great state of weakness. Transfusion was performed on May 18, in the presence of several physicians. In the morning the pulse was 74; respiration 16; temperature 37.2° Cent. (98.96° Fahr.). The lamb was four weeks old. The operation was commenced at 4.35 P.M., and lasted 160 seconds. The patient soon began to feel an agreeable warmth; then fulness in the chest; afterwards he had pains in the stomach, and general pains and distress, and said he could bear it no longer. The pulse became fuller, the face red, the breathing quick and difficult. An hour and a half after the operation there was a rigor, which lasted about forty minutes. After this followed heat and perspiration. At 8 P.M. the pulse was 95; the temperature 38.3° Cent. (100.9° Fahr.). He slept well during the night, and on waking in the morning felt better. There was more colour in the face; his appetite and strength were improved. In the end, however, there was no permanent benefit; for on May 6 the patient is reported as being about the same as before the transfusion.

The third case was that of C. M., aged thirty-seven, a shoemaker, who came to St. Rochus Hospital with cough, great debility, etc.; pulse, 80; morning temperature 36.2° Cent. (97.16° Fahr.). Transfusion was performed on May 30, at 3.30 P.M. During the operation he suffered much from pains in the back, chest, and stomach. Rigors set in in half an hour, and lasted about an hour. At 5 P.M. the pulse was 120, the temperature 40.6° Cent. (105° Fahr.); at 8 P.M.—temperature 38.5° Cent. (101.3° Fahr.); at 12 P.M.—temperature 36.5° Cent. (97.7° Fahr.). He slept well. In the morning the temperature was 36.6° Cent. (97.9° Fahr.); the pulse 80. The wound in the vein became inflamed, but it soon subsided. On June 6, the patient is reported as being improved, and having less cough and expectoration; but, as in the previous case, there was no permanent benefit.

The fourth case was that of Elise H., aged thirty-three, a nun, who entered the hospital on October 22, 1872. She was very weak, anæmic, and hysterical; had vague pains in all parts of the body; could not walk, and was often convulsed—the convulsions being of a tetanic type. As all the usual remedies proved of no avail, transfusion was tried. The operation was performed on May 30 at 4 P.M., the same lamb being used as that employed in the third case. Just before the operation the temperature was normal (37.2° Cent. = 98.96° Fahr.); the pulse strong (72). After a few seconds the patient said the arm felt warm, and complained of pains in the back and head. In about two minutes it was found that the blood had ceased to flow, owing to clots having formed in the instrument. This was rectified, and at 4.30 the operation was renewed and lasted fifty seconds. After ten seconds she said she was becoming warm, and then that she had pains in the stomach and head. In thirty seconds there was oppression of breath, and after fifty seconds she cried out that she was choking and could bear it no longer. Transfusion was at once stopped, and the patient placed in a half-sitting posture. The face was very red, the breathing short and difficult, and the pulse slow and hard. Suddenly a great change came over her, and she appeared as if dying. The face became cyanotic, the features shrunk, the nose pointed, the eyes sunken, the forehead and other parts of the body were laden with

perspiration, the head sank back, there was no radial pulse, the skin was cold, the respirations thirty-six, and there was foaming at the mouth. Auscultation showed weak tumultuous heart-sounds, and much wheezing. She appeared to be conscious, but could not speak. It was thought to be embolism. Wine, ether, and coffee were given freely, and sinapisms applied to the chest and legs. Under the impression that too much blood had been transfused, the vein in the arm was re-opened, but only about half an ounce of blood flowed slowly out: an attempt was also made to galvanise the phrenic nerves. After employing various remedies for about an hour there were signs of improvement, and at length the patient could speak. The pulse became perceptible at the wrist, but the extremities remained cold. The cyanosis gradually passed off. At 6.30 she had a rigor, and said she was freezing. This lasted until 8.30. At 9.30 the danger seemed over, the pulse was regular but weak, the breathing quieter, and she was able to talk about her condition. At her own request she had a dose of morphine, which acted well. On May 31, she had had a good night and felt better. The urine contained blood. This continued three days, and afterwards albumen was found in the urine, with fibrinous casts, as if from nephritis. This lasted more or less till June 20. For about three weeks after the operation the temperature was nearly normal, and the pulse from sixty-eight to eighty-eight. On June 1 the catamenia appeared eight days before the usual time, and for the next ten days there was a good deal of sickness. On June 13 she had erythematous spots in different parts of the body, and there had also been some cough and expectoration. On June 20 the previous symptoms had disappeared. The wound in the vein had healed, and the patient had returned to nearly the same condition as before transfusion.

[These cases do not say much for transfusion as a curative agent. It may be that the cases were badly selected, for the Italian physicians continue to extol the advantages of lamb's blood transfusion, and accounts of successful cases are frequently appearing in their public as well as medical papers. It is to be observed, however, that in Italy they do not push the operation so far as is done in Germany. As a rule, the Italians do not inject more than about half the quantity of blood (obtaining better results, and without rigors or hæmaturia) that is generally used in what is called Hasse's method, in which a point is made of continuing the transfusion until symptoms of distress appear. The details of the last case related are interesting, as showing some of the untoward phenomena that occasionally follow transfusion. The operation evidently has its dangers, some known, and some, perhaps, as yet unknown.—*Rep.*]

HENRY M. MADGE, M.D.

PIETRA SANTA ON A RATIONAL TREATMENT OF PULMONARY PHTHISIS.—In a note presented to the Paris Academy, the author upholds the doctrine of curability of pulmonary phthisis, after combatting the German theory of cellular proliferation and the fatalism of Broussais' school. For him, pulmonary phthisis is essentially a general and constitutional affection, a profound alteration of the acts of nutrition, a malady of the blood. Therefore there is no panacea for a malady (symptomated by enfeebled vitality), of which the several phases of evolution form as many distinct morbid entities. There can be no antidote for a morbid diathesis, pre-existent to local anatomic lesions which characterise the

affection. The unique specific for pulmonary phthisis is an intelligent and rational association of that collection of medicaments of which experience and chemical observation have made known the efficacy. The matter may be included in these precepts:—

1. To call to aid, during all periods of the malady, all hygienic resources—moral and hygienic treatment, pure and renewed air, tonic alimentary regimen, moderate exercise, lactic diet.

2. To utilise mineral-waters—sulphuretted, arsenical, chlorides.

3. To call to assistance the salutary effects of change of place, sojourn in temperate climates in winter, in mountainous countries during summer.

4. To neutralise the morbid ferments that engender in the organism purulent absorption, and lead to establishment of tuberculous matter. This is effected by the administration of hyposulphites and of alkaline and terrous sulphites.

5. Never to neglect the numerous general therapeutic agents, when these tend to combat the complications inseparable from each period of the malady.

PAGET HIGGS, D.Sc.

CHARCOT ON HYSTERICAL HEMIANÆSTHESIA.*—I wish to dwell particularly upon two subjects in this and the following lecture—hysterical hemianæsthesia and ovarian hyperæsthesia. I bring these two symptoms together because, generally, they are associated in the same patients.

In order to keep within bounds, I will consider only complete hemianæsthesia, as it is seen in severe cases. Even with such a severity, it is a frequent symptom, since M. Briquet found it ninety-three times in 400. The same author found it seventy times on the left, and twenty times on the right.

You know how it is in such cases. The two halves of the body being supposed separated by an antero-posterior plane, all one side—face, neck, trunk, etc.—has lost its sensibility, and, though very often only the superficial parts (external covering) is affected, sometimes the deeper portions (muscles, bone, joints) are also invaded.

Hysterical hemianæsthesia is complete or incomplete. Analgesia, with or without insensibility to heat and cold, thermoanæsthesia, is one of the most common varieties. The clearness with which the anæsthetic parts are separated from the healthy is an important character in the hysterical hemianæsthesia. On the head, face, neck, trunk, the demarcation is perfect, and corresponds almost exactly with the median line. Deserving of mention, also, is the paleness and relative coolness of the anæsthetic side. The ischæmia may be shown by the difficulty there is in severe cases of drawing blood by a pin-prick from the anæsthetic parts.

I noticed this formerly when, having applied leeches to a patient attacked with hysterical hemianæsthesia, I noticed that the bites scarcely bled on the anæsthetic side, while on the healthy side the blood flowed as usual. This ischæmia may explain certain facts considered miraculous, as in the epidemic of Saint Medard, sword thrusts did not draw blood on those attacked with convulsions. It is only necessary to suppose that these were subject to hysterical anæsthesia, and that the sword was not thrust in too deeply.

The mucous membranes are attacked on one side

* Translated and condensed from *Leçons sur les Maladies du Système Nerveux*, by J. M. Charcot. By S. G. Webber, M.D., *Boston Medical Journal*.

of the body, like the external covering. The organs of sense themselves are affected to a certain degree on the anæsthetic side. Taste may have disappeared on the corresponding half of the tongue, from the tip even to the base. The sense of smell is blunted; sight is notably weakened, and, if the left side is affected, it may offer a very remarkable phenomena, which M. Galezowski has called achromatopsia. We will return to this again.

The hysterical hemianæsthesia does not seem to affect the viscera. Thus the ovary may be hyperæsthetic, very painful on pressure, even when the corresponding abdominal wall is absolutely insensible. The ovarian hyperæsthesia and the hemianæsthesia occur on the same side, and if the former is double, the latter is usually generalised, and, consequently, affects nearly the whole body. When paresis or contraction supervene, it is always on the side of the hemianæsthesia.

The hemianæsthesia is so much the more important as it is very nearly a permanent symptom, varying only in degree, and in the intensity of its phenomena.

It is important not to forget that it is a symptom which must be sought. Many patients show great surprise when its existence is revealed to them.

As to how far hemianæsthesia, as above described, is peculiarly a symptom of hysteria, it is very seldom that it can be found with the full combination of its characteristics, caused by any other disease. If it then is well-marked, it is a valuable indication, and it will often reveal the nature of a large number of symptoms, which, otherwise, would remain doubtful. This is not absolutely true; it is especially not correct to say that 'hemianæsthesia, arising from encephalic lesions, always differs from hysterical hemianæsthesia, in that in the former the skin of the face does not participate in the insensibility,' or that, 'when it exists it is never on the same side as that of the limbs.' This is an error which has been reproduced in these very words, in the interesting thesis of M. Lebreton.

In cases which are, indeed, exceptional, but, yet, perfectly authentic, certain limited cerebral lesions may give rise to hemianæsthesia, with all the characteristics recognised in hysteria, or very nearly so.

The classical doctrine, at least, with us, is that cerebral lesions, occurring in foci which seriously affect the motor power, are almost without influence on the sensibility, especially when situated in the optic thalamus and corpus striatum.

When the lesion occurs suddenly, causing an apoplectic attack, the most marked symptom is a hemiplegia, more complete in the upper limbs, and accompanied with relaxation. In the face, the buccinator and orbicularis oris are generally affected; the tongue is also protruded towards the paralysed side. The vaso-motor nerves are also paralysed, as is shown by an elevation of temperature in the paralysed limbs.

The sensibility is not appreciably changed, or, at least, not permanently. There is no change in the special senses, unless there is some complication, as embolism of the central artery of the retina. Such is the combination of symptoms found in the vast majority of cases of hæmorrhage or softening, affecting the parts of the encephalon referred to. But by the side of the rule is a list of exceptions. There are cases, and I have seen several, where the sensibility is chiefly affected, and the anæsthesia persists, even after restoration of motion.

These alterations of sensibility may have the following characteristics: The anæsthesia affects all of

one-half of the body, being arrested exactly at the median line. The corresponding half of the face, both skin and mucous membrane, is insensible, exactly as in hysterical hemianæsthesia. It is possible, then, to observe analgesia and thermo-anæsthesia with preservation of tactile sensibility. Finally, there are, also, rare cases where, probably, the special senses were affected on the same side with the hemianæsthesia.

Almost always, when the hemianæsthesia has these peculiarities, the lesion is either entirely, or nearly so, limited to the optic thalamus. It is necessary to conclude from this that lesion of the optic thalamus is the veritable organic cause of the hemianæsthesia in all these cases?

[Then follows a brief statement of the principal arguments for and against this proposition. He concludes.]

I believe, from the preceding, that in the cerebral hemispheres there is a region, the lesion of which causes hemianæsthesia; the limits of that region are known approximately, but the localisation cannot be more clearly defined, and no one can say whether it is the parts of the optic thalamus, or of the internal capsule, or of the centrum ovale, or of the third nucleus of the corpus striatum, included in that region.

A case is referred to, in which there was trembling, resembling paralysis agitans, on the same side with the hemianæsthesia, where the special senses were affected, there being amblyopia, loss of smell and of taste on that side. He concludes, therefore, that it is very probable that complete hemianæsthesia with disturbance of the special senses, just as it is seen in hysteria, may arise, in certain cases, by a localised lesion of the cerebral hemispheres.

SURGERY.

BOUTELLE ON EMPYEMA TREATED BY FREE INCISION.—Dr. J. T. Boutelle (*Boston Medical and Surgical Journal*, October 22, 1874) reports the case of a boy, aged nineteen, who, after repeatedly catching cold, was compelled to take to his bed, with fever, severe pain in the right side, etc. When first seen, he had been in this condition for six weeks, and was greatly emaciated, had a marked hectic flush, and was sweating profusely both night and day. The physical signs showed that there was a large collection of fetid pus in the right pleural cavity, and an opening in the lung itself near the apex. He was first tapped with an aspirator between the seventh and eighth ribs, about two inches from the lower angle of the scapula, and three pints of brown, fetid, thick, frothy pus were removed. Stimulants and nutrients were ordered in large quantities, and his condition improved somewhat. Four days later, an operation was performed for the purpose of establishing permanent drainage. A knife was passed between the eighth and ninth ribs, about an inch to the right of the lower angle of the scapula, into the pleural cavity, and the incision slightly enlarged on withdrawing the blade. No pus escaped. An India-rubber drainage-tube was then pushed in about five inches, and secured by straps of adhesive plaster. The pump of the aspirator was attached to the tube, but no pus could be drawn through. After injecting a little warm water, without helping matters, the tube was drawn out, the clots were removed from its calibre, and it was re-introduced, but still no pus could be drawn through it. The tube was removed,

and a cannula introduced, but with no better result. As the patient was growing very weak, crying out with pain, and threatening to faint, the cannula was removed, and a poultice applied over the incision.

After an interval of five days, during which his condition rather deteriorated, it was decided to give ether, and to make an opening between the ribs large enough to give exit to pus. A trocar was thrust between the seventh and eighth ribs, at the point where pus had been first found, and, as it began to flow through the cannula, the latter was removed, and an incision three inches long was made through the skin, the point of puncture being at the middle of the incision. A careful dissection was made down to the pleura, the cavity of which was opened by an incision of two and one-half inches. About three pints of fetid pus escaped. On examination with the finger, a long, smooth line of adhesion was found a few inches below the incision, passing downward and backward, evidently the bottom of the sac of the abscess.

For nearly two weeks after this operation he continued to do well, his appetite being much improved. It was then found, however, that the opening in the pleura had entirely closed by granulations. The patient was again etherised, the union was easily broken up with the finger, and an opening made the length of the original incision. Not much bleeding. About a pint and a half of excessively fetid pus escaped. An India-rubber tube was then inserted, and the cavity thoroughly syringed out with warm water containing a trace of carbolic acid. The tube was then fastened in by adhesive strips.

The same treatment was continued, the thorax being washed out daily with warm water; but the patient gradually sank, and died about three weeks after the last operation. No traces of tubercle were found in the lungs.

Dr. Boutelle calls attention to the following points:

The condition of the patient; the long duration of the disease, the excessive sweating, painful bed-sores, and general prostration rendering it a most unfavourable case for operation:

The immediate relief and gain in strength which followed the evacuation of the pus, the general condition steadily improving up to about two weeks before his death:

The rapidity with which the large incision granulated together, which shows the necessity of guarding against this at the time of operation, by stuffing with lint, or inserting tubes:

The absence of tubercular deposit in the lungs after so much inflammatory disturbance:

The result of the second operation, when no pus was evacuated, showed that it is not always safe to enter the thorax very low down. The autopsy showed that this point was nearly two inches too low to enter the cavity.

SIMS ON THE MANAGEMENT OF THE PEDICLE IN OVARIOTOMY.—Dr. Marion Sims stated recently at the New York Academy of Medicine that he was satisfied that the practice of securing the pedicle with a silver wire, and returning it to the abdominal cavity, is wrong. That was the plan, however, which he adopted for twenty years; but he had been led to abandon it for the reason that secondary hæmorrhage had followed its use in two cases, in which he had seen the *post mortem*, and he abandoned its use at once. As soon as the silver wire was dropped, he resorted to the method of treatment

adopted by Dr. Peaslee at once, and continued that up to a certain date. One day he had a somewhat broad pedicle to deal with, and he introduced a double ligature; and tied one-half of the pedicle with a silk thread, and the other half with the catgut ligature. At *post mortem* examination he had found to his horror that the end of the stump was in a sloughy condition. From this case he hesitated with regard to the use of the ligature and return of the pedicle to the abdominal cavity. That sloughy state of the distal end of the pedicle was immensely suggestive. Now, to-day, he was of the opinion that securing the pedicle with the iron wire, which answers all purposes of a clamp, and keeping the pedicle outside, is the best method of management. With this view he had very much to retract of what he had said concerning the clamp in former years.

I now feel satisfied that the method introduced by Baker Brown will finally be accepted as the best, and that is the use of the actual cautery. When we get instruments perfected for applying the cautery, he believed it could be accomplished with great safety and certainty.

He proposed to have made a clamp with a gutter, so that when the pedicle was cut off even with the upper surface of the clamp, an extensive surface would be left behind for the application of the cautery, and when such a large surface of the stump had been well seared, it would be returned to the abdominal cavity. He believed that a clamp could be constructed upon this plan, which would give sufficient surface for the cautery to act upon to prevent all possibility of secondary hæmorrhage.

Dr. Sell believed that every ovariologist should go to his operations prepared for any emergency, and then use his own judgment as to whether he would adopt one or other method of treating the pedicle. He remarked somewhat at length upon the percentage of mortality attending the various methods of treating the pedicle, and concluded by saying that he was simply prefacing himself, as he purposed to review the subject in a paper at some future date.

Dr. Peaslee remarked that he used the ligature because he had never had it *slip* or *give*, if the precaution had been taken to leave the stump undisturbed after the application. He had never had a case die from hæmorrhage when the ligature was properly applied and the pedicle left undisturbed, and had never seen any indication of sloughing where the ligature has been applied. But if these accidents do sometimes occur, the same thing occurs after the use of the clamp and other methods.

FOSTER ON UNSUSPECTED CALCULI IN THE BLADDER.—Mr. John Foster reports (*The Lancet*, October 10, 1874) the case of a gentleman, aged seventy-six, who had a narrow stricture at the orifice of the urethra. He had considerable frequency in making water, but had suffered no pain, and never passed any blood. The stricture was divided, and a catheter introduced to ascertain if he emptied his bladder. With the urine came a large number of very small calculi, and, by injecting warm water, over a thousand were washed out. They had never caused him any inconvenience.

PSYCHOLOGY.

KRAFFT-EBING ON DEMENTIA SENILIS.—It is well known, says Professor Krafft-Ebing, in the *Irrenfreund*, no. 5, 1874, that diseases of the mind

may occur at all ages. Cases of senile insanity occasionally recover, but more frequently they result in exhaustion, or in rapid transition to utter fatuity. These conditions must be clearly distinguished from a complex series of psychic symptoms peculiar to the aged, seen in the expression of a senile involution of the brain coming on sooner or later, and which, both by the *post mortem* appearances, which agree in nearly all the cases, and by the extreme dementia to which they lead, form an exclusive disease, named 'senile dementia.'

The exact age at which this fatuity of the aged appears is difficult to determine, for the earlier symptoms are obscure, often only seen by a gradual change of the whole life and character, and by a transition into the physiological results of old age, viz., weakness of the memory and the will, conceit, egoism, and distrust of surroundings. This senile degeneration seldom occurs before the age of fifty, and then only as a result of typhus or other chronic constitutional processes which give an impulse to the feeble nutrition and regressive brain-metamorphosis. In the absence of such spur, and where dementia senilis is developed spontaneously, it is seldom seen before sixty to sixty-five years of age. No predisposition to it appears in one sex above the other. Hereditary taint is of little importance, and the causes seem to rest less on the objective conditions of life than on internal organic changes. The proximate cause is disturbed nutrition of the brain from insufficient blood-supply, owing to fatty degeneration of the heart and atheroma of the carotids and cerebral arteries. This rests on *post mortem* investigation, which discloses compensatory thickening of the skull, collections of serum in the arachnoid and ventricles, œdema of the pia mater, dilatation of the vessels, adhesion of the membranes to each other and to the bone, the intensity of the symptoms usually going hand-in-hand with the extent of the atrophy. The frontal convolutions show the signs most clearly, for the divisions between the convolutions are for the most part obliterated, and these are yellow. The microscope shows changes in the ganglion-cells of the cortex and in the vessels, simple atrophy, fatty and pigmentary degeneration, with occasional cysts and other coarse disease, embolisms, hæmatomata, etc.

The first signs of approaching failure of intellect are in the memory. Whilst that for past events remains, that for recent ones is destroyed. The patients are distracted, count all events the same, and do not know when they did this or that; and this amnesia may extend to a period of the last ten years. They dream over again the dream of life, and live in a time gone by. Consciousness as to past and present events is also affected, and this shows itself in a habit of wandering, or straying. They will go to strange houses, taking them for their own, and possess themselves of other persons' effects under the same error. Mistrusting everybody and under delusions of persecution, they accuse their servants of dishonesty. Güntz says that they show a predilection for abstracting keys from places where they have no business. Maniacal and melancholy symptoms, partaking in character of the peculiar form of psychic weakness, supervene at times. At the commencement and in the course of the disease, phases of maniacal exaltation consisting of aimless wandering, motiveless business, loquacity, come on; and they get up in the night and forage about the house, the great lesion of consciousness and memory being apparent in their not knowing where

they are, nor where they have put their clothes. Sexual propensities, with inclination to excess in this direction, revive, and they not unfrequently beget children. Very often melancholia shows itself, consisting of sinking feeling at the chest and hypochondriacal sentiments of death, treachery, etc., leading at times to refusal of food and accompanied by delusions of persecution, hallucinations of hearing, etc.; but these latter are fragmentary and disconnected. Under the influence of these hallucinations they get up at night, barricade the doors and windows, call for the police, etc.; and as they alternate between expansive and repressive delirium, they will address the same person at one time as 'my lord,' at another as 'an abominable pest.' These delusions vanish as the intellect becomes weaker, the patient becomes incoherent, unclean, and finally lost to all outward impressions. Motor affections are common, and consist, besides the senile tremor which is not as yet sufficiently well explained, of paralysis of the tongue, hemiplegia, and such like results, due to embolism, congestion of the circulation, hypertrophy of the heart, etc. The course of the disease is chronic, on an average two to five years. Death ensues usually from brain-complication or pneumonia. Remedies are useless, but a nutritious diet, with moderate supply of stimulants, is desirable. Since the conditions depend chiefly on cerebral anæmia, the restless condition at night is explained, and this is best combated by a slight stimulant at night, and a moderate dose of opium. Chloral hydrate is less to be recommended, because of the brittle state of the vessels and the fatty degeneration of the heart.

[The description above given represents faithfully many persons who, on account of the inability of their friends to manage them at home, are sent to asylums. The feebleness of mind being the result of a physiological change, it seems rather hard that they should come under the legal conditions of lunatics. Yet such is the case. Unless great care be taken, the fact of a person suffering from loss of memory and incoherence, due to natural decay of the faculties, may lead to erroneous statistics. For instance, a man at thirty will beget a child, sound in every way; but the father at the age of sixty or sixty-five, owing to atheroma of the vessels, a physiological change of old age, loses his memory and takes to wandering. He is, the friends being unable to keep him, put away in an asylum, and, if the son should afterwards become the subject of disease, the fact of his father having been 'in an asylum' is noted and hereditary taint supposed, where in reality not the slightest ground for it existed. No doubt, persons the subjects of dementia senilis require extraneous aid, which can be properly afforded only by asylums or similar institutions; but the reporter wishes to point out how necessary it is in estimating the question of hereditary taint in insanity, to bear in mind the fact that it by no means follows that because a person is confined in an asylum therefore his family is imbued with hereditary taint. —*Rep.*]

CHRISTIAN ON PACHYMENINGITIS IN THE INSANE.—In a work published in 1864 at Strasbourg, on 'hæmorrhagic pachymeningitis,' Dr. J. Christian gave a complete history of this pathological occurrence. Subsequent observation has confirmed what was there written (*Annales Médico-Psychologiques*). Pachymeningitis is inflammation of the dura mater,

characterised anatomically by production of cellular new membranes, generally vascular, on the internal face of the dura mater.

Observations made in Germany and France have shown the important part this inflammation plays in the production of intra-arachnoid meningeal hæmorrhages; so much so, that the history of the two cannot be separated, depending as they do on one and the same affection of the membranes. But first, as the new membrane can exist and be developed without hæmorrhage, so blood may be effused into the cavity of the arachnoid without new membrane; for, if a vessel of the dura mater, or one of the sinuses be ruptured, hæmorrhage will follow without any inflammation. These solitary hæmorrhages are not rare among the insane. Calmeil has reported several; and Christian gives one occurring in an epileptic, where hæmorrhage came on during a paroxysm, after a series of attacks which had induced intense congestion. The same thing has been seen in those affected with chronic alcoholism, a condition easily explained by the fatty degeneration of the vessels. Hæmorrhage must be viewed as an accident, pachymeningitis as a disease; so in the former one sees the signs of an intense cerebral congestion, followed suddenly by those of cerebral compression, but in the latter the brain-affection is of long date, and is generally insidious and chronic in its course, *e.g.*, the patient may have had transitory congestions, incomplete hemiplegia disappearing and then reappearing; he falls into a state of marasmus, and after death are found new membranes more or less developed. Pachymeningitis is not uncommon in the insane. It is chiefly met with in general paralysis, where Baillarger has noted it once in eight cases, Brunet once in five cases, and Christian once in three. But it may also occur in mania, dementia, etc., and in all the cases where it is met with other lesions are seen, either of the brain or membranes, and especially of the vascular system; to such an extent, indeed, that it would appear that it may supervene as a complication of any chronic malady of the nervous centres. In the insane it comes on in two different ways: 1. Either as an ultimate accident, and here one finds only rudimentary new membranes mixed with recent effusions of blood; or, 2. It occurs during the insane state, following a chronic course and becoming possessed of considerable development. In this form there are some symptoms peculiar to it, influencing to some degree the course of the delirium, at least in certain cases. Then follows the history of three insane persons, who from different causes were in a state of profound cachexia followed by development of false membrane. How does the cachexia act? Is it by a lesion of the vessels, or is it from an alteration of the blood? Does it determine ulceration of the epithelium lining the inner face of the dura mater, which constitutes the so-called parietal layer of the arachnoid? However it may be, there seems to be a direct connection between cachexia and the effusion of false membrane, and this relation is furthermore borne out by the fact that the acute maladies in which pachymeningitis has been seen are precisely those in which rapid deterioration of the blood ensues, such as typhus, variola, scarlatina, etc. These recent cases have given rise to endless discussions as to whether the hæmorrhage precedes the membrane, or whether the latter is first and causes the effusion. The theory that the new membrane is

formed at the expense of the clot is no longer held now, for neither the fibrine nor the other materials of the blood are susceptible of organisation. But how is it to be understood that a fine delicate membrane, hardly organised at all, can give out a considerable quantity of blood? This question, which is not of primary importance, cannot be answered absolutely in one sense or the other. The new membrane is formed on the inner surface of the dura mater, and the vessels which are there developed anastomose with those of the dura mater, rudimentary though the former may be. If then by any chance the dura mater become congested, there is every chance that a rupture will take place in the direction of least resistance, *i.e.* in the walls of the new vessels. Hence the effused blood comes both from the new membrane and from the dura mater. One of two things is sure to happen—either the effused blood will be small in quantity and the new membrane will imprison the clot, or the hæmorrhage may be large, and, breaking down the cellular network, will be poured into the arachnoid cavity, and then the new membrane, drowned as it were in the effusion, may be undetected. Then follows a report of some cases where the pachymeningitis occurred in very feeble and cachectic patients, but where, supervening early, it had plenty of time to develop itself, and, indeed, to influence the course of the symptoms. In one of these there was a double hæmatoma aurium.

It appears to Dr. Christian that the delirium, in cases complicated with this peculiar product, is very wild and diffuse in its nature, and is attended with rapid marasmus, incomplete hemiplegia, and periods of coma, lasting for a time and then disappearing in accordance with the various hæmorrhages as they occur and subside. T. C. SHAW, M.D.

DERMATOLOGY.

AUSPITZ ON THE EFFECT OF VENOUS OBSTRUCTION OF THE SKIN.—Dr. Auspitz has lately brought before the k. k. Gesellschaft der Aerzte in Vienna some observations on the effect of venous obstruction upon the skin, which are reported in the *Allgemeine Wiener Medizin. Zeitung* for November 3.

1. A ligature was tied round the arm of a healthy person, as if for bleeding. First the superficial veins swelled, then a livid colour spread over the arm, beginning on the flexor surface (where the skin is thinnest) and at last affecting all but the volar eminence (the thickest part of the skin). At the same time the temperature sank. The next effect was oedema of the skin, followed in from five to ten minutes by the appearance of numerous patches of red or brownish-red colour, accompanied by minute spots, which were either bright scarlet or purple in tint. On removing the bandage, the cyanosis first disappeared, then the oedematous swelling; next the red patches gave place to a diffused blush of the whole arm; and lastly this disappeared, leaving only the minute red spots, which remained for several hours or even days. Comparing these appearances with those observed by Cohnheim in a rabbit's ear as the result of mechanical venous obstruction, there can be no doubt that the minute red spots above mentioned are extravasations, either of red blood-corpuscles or of their hæmoglobin in solution.

2. Similar experiments were next tried by Dr. Auspitz on the arms of persons suffering from measles, variola, and other cutaneous diseases.

a. In the cases of measles, it was observed that the large red patches above mentioned coincided with those of the eruption; and that, beside the minute ecchymoses, larger spots of cutaneous hæmorrhage sometimes appeared.

b. The effect in cases of urticaria was less marked. The wheals were more prominent, and minute ecchymoses were not more frequent (perhaps less so) than in the normal skin.

c. In ordinary small-pox, there was intense congestion of the bases of the pustules, and the points of cutaneous hæmorrhage were both more numerous and larger than in a normal arm; but there was never any extravasation of blood in the pustules themselves.

d. In cases of hæmorrhagic variola, the whole of the arm below the ligature became rapidly covered by a dark-blue lividity, which concealed all minor shades of colour. This was the case even when there were few or no pustules; and when these were present, they were not themselves the seat of extravasation of blood.

e. The ligature applied to the arm of patients suffering from scarlatina had little or no effect beyond that observed in the control experiments above noted on the normal skin.

f. In 'scorbutic affections—*Erythema nodosum*, *Morbus maculosus Werthoffii*, *Purpura rheumatica* and scurvy proper'—Dr. Auspitz was surprised to find the effect of the ligature trifling. There was no scarlet injection of the skin and no ecchymosis. This seems to confirm the old belief (recently called in question by Cohnheim) that purpura depends on a change in the blood itself, and not on any difference of pressure in the circulation or on anatomical lesions of the blood-vessels.

OPHTHALMOLOGY AND OTOTOLOGY.

GIRAUD-TEULON ON THE ATTITUDES ASSUMED BY PATIENTS WITH PARALYSIS OF ONE OR MORE OF THE MUSCLES OF THE EYEBALL.—The paper on this subject (*Annales d'Oculistique*, July and August, 1874), is the thesis which was read by M. Giraud-Teulon before the Académie de Médecine, on the election of its author as a member of that body.

The obscurity which pervaded the writings of the older physicians on the subject of paralysis, or of paresis of the ocular muscles, has been dispelled before the painstaking observation of later inquirers, and has been replaced by a classification as exact as it is simple. The existence of a paralysis, or even of a paresis, may be foretold by the occurrence of diplopia, so that in one sense the two may be said to be convertible terms. It is the object of this paper to draw attention to the attitudes which the sufferer from any of the various forms of paralysis

will assume, for these attitudes will vary with each different form of the affection; but they will follow certain laws which admit of being formulated, and of being definitely stated. By the study of these laws of movement, Giraud-Teulon believes that it is possible to determine the exact seat of the lesion in any given case; and in this study we have, he thinks, a means of diagnosis second only in importance to the analysis of the diplopia, affording, as it does, very valuable indication as to the strength and the kind of prism which will afford relief. It must, however, be admitted that the power to use such knowledge will require an amount of penetrative observation which is not often to be met with.

When there is paralysis of any one of the ocular muscles, every effort in the direction of the action of that muscle must result in diplopia; if then a paralysis fall upon a muscle whose action is to the right, all objects situated to the right will appear double, and *vice versa*; or when the direction of action is upwards or downwards, the same thing will occur. The half of the field of vision on the side opposite to the weakened muscle will, of course, be free from double images, which are so annoying, that the patient is not long in making the discovery, and by a movement of his head he will endeavour to bring objects within this portion of his field of vision wherein diplopia does not exist. Thus, when the head and face are turned to the right, it is because the left half of the field is free from double images, and *vice versa*; and for similar reasons if diplopia existed above or below the horizontal line there would be corresponding and compensating movements of the face, either upwards or downwards. Patients make this discovery, and obviate some of the annoyance of diplopia by a kind of instinct; it is a common observation that any movement of the eyes is intimately associated with corresponding movements of the head and neck, and all that a paralytic does, is to exaggerate these movements; when, for instance, there is a want of power in the left eye to look to the right, the left half of the field is without diplopia, and so the patient, by instinctively turning his face to the right, endeavours to transpose this region of normal vision to the median line. In the case of a failure of one of the recti muscles, the direction of whose action is simply inwards or outwards, the case is easily stated, and the corresponding movements of the head are at once understood; it is not so, however, when the power of looking upwards or downwards, or in any intermediate direction, is lost; for, as this depends upon the action of several muscles, the corrective movements are more complicated and are not so readily unravelled. They do occur all the same, and admit of analysis in a similar way. Thus when the power of upward vision is lost, there will be double images of unequal height vertically, with a lateral separation and with a certain amount of inclination towards each other, and in the patient's attitude we shall see an effort made to annul, as far as possible, these several conditions. The head and face will be elevated, and the eyes will assume a fixed direction laterally; by these means the difference in elevation, and the interval existing between the two images laterally, will be obliterated. There yet remains the third condition, the obliquity or inclination of one of the images to the other to be overcome; and this is brought about by the head being inclined to one side at the same time that it is elevated. By these movements, simple vision with associated images may be re-

stored, but as yet only in one fixed and definite direction; and the patient is now in the position of one who has lost the power of lateral vision, consequently one other movement has yet to be recorded, namely, in the position of the face which is turned to one side, so that the field of single vision is once more brought into the median line, as regards the head and the trunk. In judging of the seat of paralysis by these instinctive movements of the patient's head, it is of the last importance that the date of the affection should be known; because, where the paralysis has existed any length of time, the muscles may have undergone some amount of structural degeneration, or the antagonists of the weakened muscle may have become contracted so that the field of normal vision is permanently transposed to one side or the other, and under such circumstances it would be unsafe to speak too positively of the seat of the original lesion.

BOWATER J. VERNON.

WREDEN ON MYRINGOMYCOSIS ASPERGILLINA.—Dr. Wreden, of St. Petersburg, gives, in the first number of the fourth volume of the *Archives of Ophthalmology and Otology*, the results of his observations on the fungi of the ear. He has had seventy-four cases of myringomycosis, in which he found *Aspergillus nigrificans* forty-nine times, and *Aspergillus flavescens* twenty-four times, the remaining case showing the ascomycete form of the aural aspergillus, hitherto undiscovered in the ear, which, on account of its intensely red colour, he named *Otomyces purpureus*. He considers that the aspergillus, with its different varieties and fructifications, must be designated the specific aural fungus; that the false membrane developed in the affection is usually moulded into a cast of the membrana tympani and the acute angle formed between it and the inferior wall of the auditory meatus, and that the formation of this false membrane is unattended by any otorrhoea of a purulent nature. 'The fungous growth never causes a real purulent otorrhoea.' He has not seen a single case in which, during a profuse purulent discharge, a fungous growth has been developed, though he has seen frequently a slight serous or mucous discharge present in a case of myringomycosis. He likens the external surface of the false membrane to a piece of fat pork, while the inner surface shows bright yellow or black spots, often arranged in circles, the solitary case mentioned above being of a purplish-red colour. In all cases where fungi have been present in the ear for some time, some morbid symptoms, either subjective or objective, are found. Dr. Wreden still holds his formerly expressed opinion, that these fungi are true parasites, and not merely mouldy saprophytes, that is, fungi which inhabit only dead organic matter.

W. LAIDLAW PURVES.

REVIEWS.

Infant Diet. By A. JACOB, M.D. Revised, enlarged, and adapted to popular use by MARY PUTNAM JACOB, M.D. New York. 1874.

Although this little book is expressly said not to be a 'mother's manual,' it yet appears, to judge from the preface, to be written for the special instruction of women. The authors repudiate with disdain the assertion of Fonssagrives that 'physiological theory is of no importance to the mother,' and maintain, on

the contrary, that 'the theory of a fact does concern every person who is interested in its application.' Consequently, they devote the present essay to an exposition of the physiological laws which regulate nutrition in early life, together with the means by which the growth and healthy development of the infant may be most successfully maintained. The authors claim for their essay that it is a 'popular' one, in that they have avoided as much as possible the use of technical language; that they have been careful to explain all things with which an unscientific person is not expected to be familiar; and that they have rigidly excluded all doubtful theories from their pages. To a certain extent this is no doubt the case: some efforts have been made—by replacing technical terms, where possible, by simpler expressions, or by explaining their meaning whenever it could be done briefly—to render their exposition intelligible to the reader: but in a book designed expressly for the use of women, much more might have been done in this! respect, and there is still far too lavish a use of scientific phraseology, and too great a tendency to encumber the explanations by over-elaboration. To give an example:—an account of the process of digestion in the child is embarrassed by a description of the human stomach; and its differences from the same organ in the carnivora and other animals, and in birds, are dilated upon. Again, a description of the digestive process itself is greatly obscured by chemical technicalities, and the use of such words as 'peptone,' 'parapeptone,' and 'metapeptone' must prove rather terrible to the unscientific mind. It is true that 'peptone' is explained to be 'a soluble product of the modified albuminoids,' but this explanation does not perhaps altogether remove the difficulty. Later on, in discussing the effects of heat upon the infant economy, the authors appear to forget completely that their observations are directed to a lay audience; the most technical language is used without stint or any attempt at explanation, and the whole passage reads like an extract from a scientific paper prepared for a medical debating society.

It is for this reason, we think, that the general tone of the essay, admirable as it is, is pitched in too high a scientific key, and that for a popular work it appeals to too narrow a circle of readers. The authors assume a degree of scientific cultivation in the reader which is certainly an exceptional accomplishment even amongst the better educated women—at least in this country, and on this account we fear their labours are not likely to meet with that general appreciation which was no doubt expected and is certainly deserved.

In itself, however, the treatise is a very useful one, and as setting forth in a clear light the laws which regulate the process of digestion in the infant, and the kind of food which best meets the wants of the system, will surely prove a valuable guide to the student and young practitioner, and form a useful preliminary to more strictly professional study of the diseases of early life.

Starting with the assumption that milk is the best food for a young child in all stages of its development, the authors first discuss the conditions regulating its secretion in the human subject. They state its composition; estimate the value of its different components; and give reasons why it is occasionally found to disagree. The anæmia and atrophy sometimes seen in sucking infants brings up the subject of rickets, and it is shown that mother's

milk is no preservative against this disease, which is merely a common expression of malnutrition in the child in whatever way that malnutrition may be induced. Human milk is then compared with cow's milk, and the causes of the frequent indigestibility of the latter fluid are explained. An account of the digestive process then introduces the experiments of Korowin, of St. Petersburg, upon the salivary and pancreatic secretions, and leads to a discussion of the desirability of starch as a food, and an inquiry into the relative value of different farinaceous materials. Digestion in the stomach is described at considerable length, and some of the causes which interfere with that process and lead to vomiting are touched upon. The food is then followed down into the intestines; the changes it there undergoes are described, and the arrangements which may occur, leading to flatulency, colic, and constipation or diarrhoea, are referred to. Finally there is a highly technical explanation of the influence of heat upon the young child, and the essay closes with some plain rules for the nursing and feeding of children, and for their management during the hot season.

It will thus be seen that the authors deal very fully with the subject of which they treat. The little book is carefully written on the whole, but the page is constantly disfigured by the use of the word 'that' for 'which,' an inelegance which sometimes causes a little confusion in the sense. The essay can be strongly recommended to any one who is desirous of mastering the subject of infant feeding, and who has acquired, at any rate, an elementary knowledge of physiology and chemistry. Without this knowledge little advantage could be gained from its perusal.

MISCELLANY.

A WARNING TO DOCTORS.—A warning to doctors is issued by the *San Francisco News Letter*, which announces its intention in future of publishing after each death-notice the name of the attending physician.

PHYSIOLOGY FOR LADIES.—Dr. J. G. McKendrick recently commenced in Edinburgh a series of lectures to ladies on Physiology, at which there is already an attendance of seventy-one.

WEATHER-LORE.—Professor Dove has lately published an article in the magazine of the Berlin Academy on cool Mays after mild Januaries. Herr Dove regards as proved a tendency to low temperatures in spring after warm winters. It appears that a mild January is generally followed in the interior of continents by a mild May, on the north and east coasts by a cool May, on the Atlantic Ocean again by a May milder than usual.

REMARKABLE COINCIDENCES.—One of the most remarkable series of coincidences on record is furnished by the statistics of Iowa and Georgia in the matters of insanity, blindness, etc. The populations are given as follow: Georgia, 1,185,000; Iowa, 1,182,933 (the national census made them 1,191,792 and 1,184,109 respectively), and the following were the showings of the two States as to the unfortunate classes of their population:—

| | Georgia. | Iowa. |
|-------------------------|----------|-------|
| Insane | 1185 | 1183 |
| Idiotic | 790 | 789 |
| Deaf and Dumb | 677 | 676 |
| Blind | 474 | 473 |

AN AWKWARD DRAUGHT.—Dr. G. R. Gilruth reports a case (*Edinburgh Medical Journal*, Nov. 1874), in which a middle-aged, delicate woman, feeling herself becoming

suddenly faint, seized an ordinary quart bottle, thinking it contained porter, and drank the whole of its contents, namely a pint of paraffin oil. Her mistake being at once discovered, an emetic was given, causing copious vomiting. When seen, shortly after, by Dr. Gilruth, she complained of a burning sensation in the region of the throat and stomach; the surface of the body was cold, but the pulse was good, and the fauces, with the exception of being slightly reddened, had a natural appearance. The treatment consisted in giving about three drachms of the bicarbonate of soda dissolved in a small basinful of warm water; ordering a hot poultice to be applied over the abdomen; and, later, two drachms of wine of ipecac, but without causing more vomiting. The natural warmth speedily returned to the body, the unpleasant symptoms disappeared, and in the course of a few days the woman was moving about in her ordinary state of health.

OPIUM SMOKING.—In the new series of consular reports from China, Mr. W. E. King, Vice-Consul at Kewkiang, put in a word in favour of moderate opium-smoking. In a tour on the Upper Yangtze and in Szechuen he observed that the junk sailors and others smoked with impunity. Their constitutions seemed robust, for they had prodigious appetites, and their work was very hard, lasting from 4 A.M. until dark with hardly any intermission, and constantly requiring them to strip and plunge into the stream at all hours and often in the most dangerous parts. The two persons most addicted to smoking were the pilot and the cook. On the incessant watchfulness and steady nerve of the former the safety of the junk and all on board frequently depended, and the second worked hard from 3 A.M. to 10 P.M., and often longer, and seemed independent of rest or sleep. This latter had a conserve of opium and sugar, which he chewed during the day, as he was only able to smoke at night. Consul King declares his opinion as to the mischief of opium-smoking to be much modified; he feels bound to recognise the fact that the habit can and does exist without detriment to health or capability, the opium merely affording a solace and a stimulant.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 1rs. 4d.; free by post, 1rs. 6d.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & Co., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The First Volume, containing upwards of Two Thousand Articles abstracted and compiled by a staff of Fifty Hospital Surgeons and Physicians, is now ready, price 1rs. 6d. Cloth Cases for binding the Numbers for the year 1873 are also ready, price 1s. 6d. each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & Co.—Calcutta: THACKER, SPINK & Co.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & Co.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & Co., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.
